Dr. Philander A. Harris of Paterson said, regarding absorption of the walls of the tube, that specimens of such a tube widely broken open and the major part of the fetal products lying in the abdominal cavity had been presented. He asked Dr. Rau how much blood was found in the abdominal cavity.

Dr. Rau responded that none was found.

Dr. Harris said he had operated upon as many as eleven unruptured cases, eight of which had been presented to the New Jersey Medical Society last summer, but only one had been confirmed by microscopical examination. The diagnosis rested upon the amenorrhea, the slight pains and blood in the abdomen, it escaping from the *ostium abdominale*.. He believed these were the only cases that would be called tubal pregnancies. None had severe pains, or rapid pulse, but little pains and atypical menstruation.

Cystic Tumor of Kidney.—Dr. Louis J. Ladinski presented this specimen which he had removed from a woman, fifty years old, who had been married twenty-eight years and had had seven children. There were no miscarriages and menopause occurred two years ago. Her illness began some four months ago, when she began to have pain in the left hypochondriac region, and then a mass in that region was noticed which gradually increased in size, accompanied by frequent and severe attacks of pain. There were no vomiting, chills, or fever. On admission to Beth Israel Hospital on December 29, 1905, a large nodular tumor, of apparently semisolid consistency, about ten inches in diameter, could be felt, extending from the free borders of the ribs on the left side to a point several inches below the umbilicus, and from a line several inches to the right of the median line to the lumbar region. It was freely movable in all directions and was not adherent to the abdominal parieties. The diagnosis of cystic tumor of the kidney was made. Operation was performed on January 4, 1906. On exposing the tumor it was found to be a cystic mass of the left kidney. The opposite kidney was apparently normal. The peritoneal covering of the kidney was extremely vascular, as was the capsule. The left kidney was removed. The patient made an uninterrupted and uneventful recovery.

Right Ovarian Cyst, Pyosalpinx, Intestinal Obstruction.—Dr. Ladinski reported this case. The patient was a woman, thirty years old, who began to menstruate at the age of thirteen, her last period occurring two months ago. She had been married nine years, had had two children, the last seven years ago, and no abortions, had leucorrhea for the past year, but no painful micturition. Her present history dated back two weeks preceding admission to the hospital. In view of the conflicting symptoms and physical and clinical signs, a positive diagnosis was impossible. There was a history of amenorrhea for two months; sudden collapse, with vomiting and intestinal obstruction; and pain and tenderness distributed over the entire abdomen; there were signs and symptoms of acute and general peritonitis and intestinal obstruction, with rapid pulse but normal temperature. On the other hand there was found an ovarian cyst on the right side, and an enlarged and thickened tube with moderate tenderness over the appendix and gall-bladder. The possible diagnoses were, twisted pedicle of ovarian cyst, rupture of pus tubes, rupture of tubal pregnancy, of appendix, or of gall-bladder, and intestinal obstruction due to volvulus or intussusception. He was unable to make a differential diagnosis, as he had never met with a similar case before, and he decided that this was one of the cases when one must operate first and make a diagnosis afterward. Upon operation an injected peritoneum was found; the peritoneum was incised and a left ovarian cyst was found as well as a coil of small intestine prolapsed in the pelvis and attached by slight adhesions to the fimbriated extremity of the tube. This portion of the intestine was adherent to itself and twisted in several places, forming several loops and causing a complete obstruction of the bowel at this point. The intestines were very much distended above this point and absolutely collapsed below it. The adhesions were broken up and the loops freed. The pus tube, cyst, and appendix were removed and the abdomen closed without drainage. The patient made a good recovery.

Dr. Egbert H. Grandin said that he preferred the abdominal and transperitoneal route for the removal of large tumors of the kidney. The man who knew how to keep himself clean during operations could go deliberately from above and remove such large tumors more quickly than if he chose the lumbar route. To be sure, if one operated from behind, he might not open the peritoneal cavity; if from in front he must.

Dr. C. Clarence Sichel said that when the kidney had become converted into large abscess cavities in these advanced cases, and was bound down by adhesions, he believed it would be safer to go in from the back and not open the peritoneal cavity.

Dr. John O. Polak spoke of the ease of handling these pus tumors through König's incision, through which he had removed very large kidneys, and without entering the peritoneum.

Dr. A. E. Gallant said that it was wonderful what an amount of exudate followed the removal of kidneys. In attacking large kidneys one did not always know whether he was dealing with a pus kidney or not, and, therefore, greater care should be exercised not to open the peritoneum; for this reason the lumbar route was to be preferred in order not to invade the peritoneal cavity.

Dr. Ladinski closed the discussion.

A Comparative Study of the Various Methods of Terminating Pregnancy and Labor.—Dr. S. Marx read this paper. He said that a résumé of the work done in the domain of obstetrics showed conclusively that a finality had not been reached in regard to the many and varied operations which were devised for the selfsame conditions by equally good men. The tendency to radicalism grew in proportion to the lack of skill and experience; this was evident from the reports of major work when patience and conservatism would have saved such an operation. The gynecologist and the obstetrician should work hand in hand, as in this way dystocias due to improper technical operations which were presented by the gynecologist to the obstetrician at the bedside of the woman in labor could often be avoided. He doubted whether, if these specialties were combined, the gynecologist would insist on doing his many and varied vagino-abdominal fixations. We were forced to admit that the ideal operation which would stand the test of childbirth for the various malpositions of the uterus had not yet been devised. He thought it was more scientific to do a complete hysterectomy for a uterus studded with fibroids. During the first trimester the operation of emptying the uterus differed little from a simple curetting, except that we were to be careful to remove all products of conception. He recommended the use of the sharp curette, as the cervix usually had to be dilated instrumentally. During the second trimester the preliminary tamponade of the cervix and lower uterine segment with sterile gauze should always anticipate operative interference except in cases of great emergency. This was the method of choice, whether at a later period of pregnancy or at term, in cases that did not warrant more radical measures. If at the end of twenty-four hours there was no material dilatation and urgency be present to terminate the labor, his method of choice for many years had been

the manual dilatation of the os by the power of the conated hand alone. This had never failed in an experience of several hundred cases. No woman in labor should be subjected to any operative interference unless such measures were distinctly called for by indications which were vital. The Bossi dilator was to be condemned, as in his experience the human hand had been used with far better success. As to direct operative interference in the second stage we had forceps, version, craniotomy, and the major operations. Of the greatest importance and of the greatest assistance in furthering favorable results in operations of the minor type, we had the Walcher position, which he most heartily recommended as an adjuvant to other measures. Generally a head that was engaged or could be made to engage was one that stood for forceps delivery. A version in the presence of a tetanized uterus or in the presence of a contraction ring was an invitation to a grave lesion of the uterus; hence, under these latter conditions, the application of the true high forceps above the brim was the clear indication. Operations of the major type as strictly elective measures except in extreme pelvic contractions were impracticable and almost impossible. The great stumbling block was and always would be the adaptability and size of the fetal head and its relation to the pelvis through which it must pass. There never was and never would be a question of pelvimetry or of cephalometry alone, but a mathematical proposition as to the correlation of head and pelvis. The abdominal cesarean was steadily growing in its field of utility, while the operation of symphyseotomy had fallen by the wayside. Under a true conjugate of 6 cm. the abdominal cesarean operation became an operation of necessity. He thought it a safe teaching that when forceps failed and version could not be done or was contraindicated for one reason or another, cesarean section with its limitations would stand the test of time and experience. The most difficult problem presented to the accoucheur was when not to induce labor in cases of contracted pelvis. Obstruction from soft structures, when immovably fixed, or deformity of the absolute variety, called for the abdominal method. The safest time to interfere in the lesser contractions was when by suprapubic pressure it was found that the head was just capable of being made to engage. In his experience he thought that at this time labor was best induced by the preliminary tamponade of the cervix and lower uterine zone with gauze, plus the introduction of a large-sized bougie. We were never justified in doing a cesarean section for a placenta previa pure and simple. The operation might occasionally be warranted in eclampsia. In terminating pregnancy, where there was no time for preliminary work, we could only empty the uterus by the so-called bloody methods. With the cervix drawn into the lower uterine zone we had practically three methods at our disposal, the various bags, the Duehrrsen operation, and the human hand. He preferred the hand. In the presence of a complete cervix, hard and unyielding, in a woman whose life was threatened, the only thing was a quick and conservative operation. Here we had the Bossi dilator, which was to be condemned, and vaginal hysterectomy or vaginal cesarean section, which appealed to him as a method of considerable value. His objection to this operation was the possible weakening of the uterine wall and a possibility of rupture in the event of future pregnancy. This objection had to be waived in the presence of desperate conditions. The pericervical vaginal tissue was incised and the vagina split anteriorly toward the urethra. The bladder was pushed out of the way without opening the anterior peritoneal sac. The lower uterine zone was exposed in front and behind. An incision was made into the uterine body anteriorly up to the reflection of the bladder, the membranes ruptured and the fetus extracted. If more room was desired the posterior uterine wall might be incised without opening the peritoneum. The placenta was removed manually and the wound closed as after cesarean section. A small drain was placed in the vesical space and if there was a tendency to uterine relaxation the uterovaginal tract was tamponed with gauze.

Dr. Egbert H. Grandin said that it was nearly eighteen years ago that he began to talk in the Section on Obstetrics and before the New York Obstetrical Society, along these same lines, and now he wished again to speak absolutely from the same platform that he spoke from eighteen years ago. He had seen no reason for changing his opinions in his teachings and in his practice, and he referred to certain journals, particularly the *American Journal of Obstetrics,* wherein he voiced the sentiments that he now had. He agreed with the reader of the paper that there should be a close connection between obstetrics and gynecology, and that if there were better obstetrics there would be less gynecology. He differed from the reader of the paper, however, in underestimating the value of the pelvimeter, and he regretted that the average medical man did not really know what the pelvimeter was. The pelvimeter, however, solved but one factor in the problem; and it could never solve the other, *i.e.* the size of the passenger. Dr. Grandin considered the subject of methods of induction of labor under two heads, (1) the elective, and (2) the emergency. Under the elective head he said they were dealing with cases as they dealt with interval appendicitis operations; they had plenty of time. But under the emergency head the saving of life was often a matter of time. Therefore the methods of dealing with the cases must necessarily differ. In one instance surgical judgment could be used, whereas, in the other, one must fit the shoe to the foot. He always believed in leaving everything to nature when not called upon to interfere with nature. Therefore, under elective indications (as disproportion between the passages and the passenger) what he aimed at was to cause the cervix to merge into the lower uterine segment; that could be better accomplished by leaving the case to nature and letting the woman deliver herself. There was but one rational, but one surgical, but one aseptic manner of starting labor, and that was by the use of the gauze tampon under strict antisepsis, packing the cervix up to and above the internal os with gauze, packing the vagina as well, and then placing the patient in bed; if at the end of thirty-six hours the uterine contractions had not become established one had attained a softening of the lower uterine segment, and, if one had the courage of his convictions, the only instrument, and the best one to employ now, was the finger for complete dilatation of the cervix. Then the uterus should be emptied. In all his experience after using the gauze tampon, when gestation had advanced to the seventh month, he had never failed to empty the uterus within one hour, and in 80 per cent. of the cases, when the child was previously alive at the beginning of the operation, to save that child. In the second class of cases, the emergency ones, one must meet them as they arose, and it was only a matter of time; the uterus must be emptied in a very short time and without inflicting traumatism on the woman, and at the same time paying some regard to the lesser life, that of the fetus. In dealing, for instance, with a case of toxemia of pregnancy, speed was necessary; he had seen a patient die within half an hour after the first eclamptic attack. The indication here was to empty the uterus and let the woman bleed; bleeding from the uterus itself was here indicated. With regard to the Bossi instrument, he could not conceive of its doing anything but harm.

Dr. George H. Balleray believed the pelvimeter to be a useful instrument, and said that any preconceived notions regarding it might do harm. He had known cases in which a diagnosis of contracted pelvis was made by means of the pelvimeter and a cesarean section performed, when the same woman later had a natural delivery and the child was as large as the one delivered by cesarean section. The cases in which the more active measures were indicated

were acute cases of toxemia, or hemorrhage, etc., and here one must act promptly. He believed that there was a field here for the use of the tampon.

Dr. William S. Stone said that as the result of eleven years' observation at one clinic he was certain that the number of cases brought in as the result of injuries and infections from childbirth had notably diminished, and the number of post-operative cases, too, had considerably diminished. Dr. Stone said he had used bougies, had used the gauze, etc., but the rubber bags had given him more uniform results, and it appeared to him to be a more satisfactory method, not only in his hands, but in the hands of his colleagues in the hospital.

Dr. P. A. Harris referred to the paper that he read before the Pan-American Congress at Washington, wherein he described a method of dilating the cervix, not by driving the uterus upon the conated hand, but dilating it with the forearm in a condition of repose. He stood with the gentlemen who favored digital dilatation. He had had made an instrument which he was going to present at some future time before the Academy of Medicine, which registered the exact number of pounds pressure that was being applied. There were dangers encountered when the hand was used, because it could not make the continuous pressure that an instrument with a spring could.

Dr. C. Clarence Sichel said that three weeks ago in the hospital he had a case of placenta previa, the placenta being marginal, and a tampon was used for twelve hours. The house surgeon tried the stop the hemorrhage by tamponing. Dr. Sichel, when he arrived, rapidly dilated the cervix, did a podalic version, and extracted the child. The patient died, and he believed the patient's life was sacrificed by attempts directed to stop the hemorrhage by tampons.

Dr. John O. Polak said that, in the case reported by Dr. Sichel, the tamponing was not well done, and that in such cases tamponing was the only thing the general practitioner could do. Personally he advocated the use of the bag in placenta previa; it not only acted as a tampon, but was an excellent dilator and did not subject the cervix to the traumatism that the hand did. In emergencies, though, there was nothing like the hand.

Dr. A. E. Gallant said that if one wanted to stop hemorrhage from the cervix something was wanted which would fill it up; for this purpose he advocated taking gauze, wetting it, then wringing it as dry as possible, and inserting; this gauze would swell and stop the bleeding from the cervix, but not from an accidental hemorrhage from the uterine cavity.

Dr. S. Marx said that he had been disappointed with the pelvimeter as an instrument of precision. He did not believe it was a question of pelvimetry at all; it was only the question of the adaptability of the child's head to the uterus. The pelvimeter was only one for comparison.

The Pelvis in Obstetrics, and a New Instrument for Measuring Its Diameter in the Living Woman.—Dr. Sidney D. Jacobson read this paper (see page 489).

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Regular Meeting Held February 20, 1906.

Dr. William F. Campbell in the Chair.

The Treatment of Meningococcus Meningitis in the First Medical Division of Bellevue Hospital During the Early Summer of 1905.—Dr. Edward L. Dow read this paper. (See page 495.)

Dr. William Browning said that there was little to add to Dr. Dow's eminently sane paper. There were, however, two points which required further emphasis. In the first place it is now well recognized that the diplococcus meningitis is less dangerous than any of the other forms, as the tuberculous and pneumococcus varieties. In the second place Dr. Dow failed to call attention to the possibility of spreading the disorder. In spite of the differences of opinion as to the degree of communicability of meningitis, it is necessary to take measures for preventing contagion. Dr. Browning recited a recent case in which a nurse attending a case of meningitis contracted the disease. It has always been his practice to have the patient placed in the lightest room possible, with the eyes shaded. The mechanical conditions, congestion, and stasis of the choroidal fluid are much more grave than are commonly realized, and cause many of the symptoms. He recalled the case of a robust young man who, in 1900, was seized with a severe attack of meningitis and who recovered. During the succeeding five years he was actively engaged in the arduous duties of his occupation and enjoyed the best of health. In 1905 he had another attack. But this time there were no petechiæ, no rise of temperature, and no photophobia. There were, however, nausea, vomiting, a pulse of 60, incontinence of urine, and an inability to stand without assistance. There were a slight retraction of the head and a slight swelling of the optic disk on one side. It was clear that the symptoms were due to the congestion and the collection of cerebrospinal fluid and not to an immediate infection and toxemia. It seemed as if the inflammatory changes following the first attack were responsible for the mechanical conditions of the second.

Dr. J. M. Van Cott said that the author of the paper struck the keynote when he characterized meningitis as a reactionary disease. In the cases in which death occurs early, the conclusion is inevitable that the system is swamped by the toxins of the meningococcus. This is supported by the autopsy findings. The mucous membrane of the nose and its accessory sinuses reveal extraordinary changes. In many cases the mucous membrane is literally ripped from the bone by the collection of inflammatory fluid. In this connection the speaker alluded to the fact that the life of the meningococcus is short and its pathogenicity is slight. It seemed to him as if one of the chief factors in the etiology of meningitis is the lack of resistance in the patient. Meningitis is a contact disease. The Berlin commissioner reported that the principal portal of entry for the pathogenical organism is the cribriform plate of the sphenoid. The speaker agreed with Dr. Dow that keeping high the patient's head serves to drain the bony cells about the nose and prevent the infection from traveling upward. In view of the fifty-three per cent. of recoveries that occur, as indicated by the report of Councilman, one may place a great deal of reliance upon the *vis medicatrix naturæ* in combating this disease.

Infective Arthritis Complicating Otitis Media.—W. P. Eagleton contributes the histories of a series of cases of this nature, noting that we may have a joint inflammation caused by toxins of germs which do not actually enter the joint, or they may so enter, or the joint may become involved as the result of a neighboring osteomyelitis. He believes that the ear is the most frequent source of general pneumococci infection in children. In the two latter of the varieties enumerated above, the mortality is high, and the mobility of the joint is sure to be seriously impaired, if not wholly lost. The treatment depends altogether upon the class to which the arthritis belongs. An inflammation of a joint appearing during the course of an otitis media, or a sinus thrombosis, warrants aspiration at once. If examination of the fluid by cover-slips and cultures demonstrates it to be sterile, rest, and the placing of the joint in proper position, may be all that is necessary. If overdistention by fluid is threatened, repeated aspirations may be required. Placing the joint in proper position, in such cases, is highly important, as spontaneous dislocations, from distention, have been reported. When a joint contains pus, it should be promptly opened, although cases of recovery, following aspiration, rarely occur. Nevertheless, in every case in which the aspirated fluid contains pathogenic microorganisms, even if the synovial fluid is not purulent, the best results are obtained by opening the joint and inserting a guttapercha drain.—*Archives of Otology.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Therapeutic Hints.

Itching of the Skin.—For this condition Biddle recommends lukewarm and moderately hot baths, very hot applications, and alternate applications of heat and cold, each fifteen seconds, repeated a number of times. Acid baths sometimes are of advantage, and in other cases alkaline baths are more effective. For an acid bath use the following:

℞ Ac. nitric. fort. ..... ʒ ss.
Ac. hydrochlor. fort. ..... ʒ i.
Aquæ ..... C xxx.

The following is a formula for an alkaline bath:

℞ Potassii carbonatis .....
Sodii carbonatis ..... ʒ iii.
Sodii biboratis ..... ʒ ii
Amyli ..... ʒ viii.
Aquæ ..... C xxx.

The most frequently used, and the most successful of the antipruritics, owing to their stimulating effect and to their specific benumbing of the nerves, are phenol, camphor, and menthol, but much discrepancy exists as to the strength of the ingredients, especially as regards phenol. Biddle never uses it in greater proportions than five to ten minims to the ounce, but others advocate its use as high as 20 to 30 per cent., sufficiently strong to benumb the parts. It may be incorporated in a lotion with water in the proportion of three drams to the pint with an ounce of glycerin. Camphor is usually combined with phenol in the proportion of three to one by weight, or with chloral in equal proportions. Menthol is usually used in an ointment base, or in olive oil, ten to fifty grains to the ounce. In the astringent class may be found a weak solution of alum, of citric acid, and a solution of lead, especially the subacetate, two to three drams to the pint; of dilute hydrocyanic acid, half to one dram to the pint, or pyroligneous acid, one to thirty. In the disinfectant class the best preparation is tar, as found in the liquor carbonis detergens, or liquor picis alkalinus, or naphtol. For its purely anesthetic effect cocaine is used, especially in pruritus vulvæ, but care should govern its use, for fear of establishing a deleterious habit after repeated applications. For its analgesic effect resorcin is often used in solution, as are ichthyol and nitrate of silver, the latter applied with a brush, as in pruritus ani. —*Journal of the Michigan State Medical Society.*

Frostbite.—

℞ Ichthyol.
Resorcin.
Acid. tannic. ..... aa. 10
Aq. dest. 50

Sig. Apply twice daily.

℞ Icthyol.
Ol. Camphorat. ..... aa. 5
Lanolin. 20

M. Ft. ungt. Sig. Apply night and morning.
—*Pharmazeutische Post.*

Cooling Ointment.—

℞ Acid. salicyl.
Acid. carbol.
Naphtol ..... aa. 5
Lanolin.
Petrolati ..... aa. 30
Aq. dest.
Acid. acet. dil. ..... aa. 15

Correspondenzblatt für Schweizer Aertze.

Irritable Bladder.—The following has been recommended for irritable bladder:

℞ Tr. hyoscyami. ..... ʒ i.
Potass. citratis ..... ʒ ss.
Ext. buchu fl. ..... ʒ ss.
Ext. tritici fl. ..... ʒ i.
Aquæ dest. ..... q.s. ad ʒ iv.

M. S. Teaspoonful in a wineglass of water three times a day.—*Clinical Review.*

Palpitation.—For the mildly neurotic heart Satterthwaite prefers to use camphor monobromate, especially in the fluttering heart of emotional women. It is also useful in nocturnal palpitation, such as is so frequently seen in diabetes and in aortic disease.—*Denver Medical Times.*

Facial Eczema in Children.—The following treatment is advised by Lassar for crusted eczema of the face in children: Clean carefully, oil the parts, wash without enough friction to cause bleeding, and apply the following salve:

℞ Olei. rusci
Sulphuris sublim. ..... aa ʒ ss.
Vaselini
Saponis domestici. ..... aa. ʒ i.
Cretæ albæ. ..... ʒ iiss.

M. S. Apply, cover with powder and bandage.—*Clinical Review.*

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Minnesota.—Reciprocity has been established between Minnesota and the following States: Illinois, Iowa, Kansas, Maine, Maryland, Michigan, Missouri, Nebraska, Nevada, New Jersey, Ohio, South Carolina, South Dakota, Wisconsin, and Wyoming. The fee is fifty dollars.

Nebraska.—On and after July 1 next, all applicants for a license to practise medicine in Nebraska must present evidence of having either (1) a college or university degree, or (2) a high school diploma of standard of college entrance. Failing either of these, the applicant must pass a satisfactory examination before the State Superintendent of Public Instruction.

Iowa has established reciprocal relations with the following states: On examination only with South Dakota, Colorado, Illinois, Missouri, Wyoming, Minnesota, Nevada, and New Jersey. Upon examination, or upon a diploma from a reputable medical college without examination, if the certificate was issued prior to January 1, 1899, with Nebraska, Kansas, Texas, Wisconsin, Michigan Indiana, Kentucky, Maryland, Georgia, and South Carolina.

Indiana.—The Indiana State Board of Medical Registration and Examination receives severe criticism at the hands of the *Fort Wayne Medical Journal-Magazine*. Among other charges, the board is accused of allowing the questions for a coming examination to be circulated. It is also charged that a certain medical man had been informed that for one hundred dollars he could be furnished with all the questions of the coming examination of the board.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 24, 1906.

	Cases	Deaths
Typhoid Fever	15	5
Malarial Fever		
Smallpox	1

SOME POINTS FOR DISCUSSION RELATING TO THE PREVENTION AND TREATMENT OF PNEUMONIA.*

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

My purpose this evening is to offer a few important topics for discussion, relating to pneumonia. In doing so I will open it briefly with some facts based on personal observation and experience,† together with the added experience and observation of others—to whom I owe my cordial thanks for courtesy and help.

First, then, I would speak of leucocytosis, or its absence in pneumonia. What value or assistance is it as regards prognosis or treatment in a given case?

In December, 1904, I wrote as follows:[1] "There is a point to which I would refer in connection with treatment, because from its appreciation may proceed, I trust, something of real value in prevention of imminent danger. Absence of leucocytosis in acute lobar pneumonia presages death, as hitherto observed. It behooves us, therefore, to have a careful differential blood count made as soon as the disease is at all clearly defined; and no matter how limited locally the disease may be for a while, or how little threatening at first the symptoms, we cannot be too solicitous or too watchful in such cases in our care and treatment. Several times death has followed rapidly, in my experience, and except for the known result of the blood count I should have been lulled into a false security. Later, also, we may obtain facts of great value from the differential count of the leucocytes, as we now do in appendicitis. If in the beginning, for example, we discover the polynuclear neutrophiles in relative excess and the eosinophiles notably decreased or absent, may we conclude that these are, in reality, the very serious cases, 'whether associated with increase of the total number of the leucocytes beyond the normal or not?' I must leave a positive answer for the while with my laboratory friends."

One of the best of them, in my judgment, Dr. F. E. Sondern, answers it briefly as follows, so late as November 13, 1905:[2] "The increase in the relative number of polynuclear cells is a direct indication of the severity of the toxic infection and," he adds, "the degree of leucocytosis an absolute indication of the body resistance toward infection."

The following is a report kindly sent me by Dr. G. B. Capito, late house physician of St. Luke's Hospital, on January 1, 1906. He writes: "The statements seem to be warranted. (1) Patients with low leucocyte counts, as a rule, appear to be more prostrated than those with a distinct or marked leucocytosis. (2) However, some of the cases with low leucocyte counts did not appear markedly prostrated; and cases with a distinct leucocytosis fared badly; *e.g.* one case died, another case with about the same physical signs in lungs, leucocytes 6,400-14,000, lived. (3) In one case with low leucocytes there seemed to be an improvement in the general condition of the patient when the number of leucocytes increased."

On January 18, 1906, Dr. I. Adler wrote me "that we have found in all cases of pneumonia (records of German Hospital, N. Y.), especially lobar pneumonia, provided there are no complications which might influence the leucocytosis, the leucocyte count of the greatest prognostic value. A good leucocytosis of 18,000 to 20,000 or more signifies to us a probably favorable course of the disease, while a low leucocyte count, no matter how favorable the other symptoms, means danger ahead."

Dr. Harlow Brooks "considers absence of leucocytosis in pneumonia in frank cases, as a bad prognostic sign." (From a letter to me January 26, 1906.) The results of recent studies of leucocytosis as a prognostic sign of pneumonia, according to a personal letter, dated February 11, 1906, from Dr. Augustus Wadsworth, a former member of my house staff at St. Luke's Hospital and a scientific observer of very great promise, is as follows: "A constantly high leucocytosis is a favorable sign and a low count unfavorable, but in individual cases a low leucocytosis may be due to a mild infection and the high count to a virulent infection. It is then a sign of the virulence of the infection and of the recuperative resources of the patient; extremely valuable when rightly interpreted with the other determinations of individual cases."

In order to be valuable and reliable, as regards prognosis and treatment, frequent counts should be made during the acute stage of pneumonia. Isolated counts have little real value and are frequently misleading. Counts, especially differential ones, are thoroughly satisfactory only when made by men who have extensive experience, are skilled and trustworthy, and have all desirable laboratory facilities. I consider it useless, except in extremely rare instances, for the medical practitioner, either of high or low degree, to devote the time essential to acquire the technical knowledge and facility properly to make these counts and then to make them continuously, even in relatively few instances. Therefore, it is merely conscientious in a last analysis, to our patients and to ourselves to hand over this work to those best fitted to do it, and not to trammel or attempt to control it by our own minor knowledge or power to do the practical part of the work. I, for one, claim also that we who do not perform the actual laboratory work are far better able to estimate its clinical importance than anyone, no matter how versed in constant laboratory work, even of the best sort, can be who is not brought into frequent daily contact with patients. And to unite the two

* Read at a meeting of the Practitioners' Society of New York, March 2, 1906.

† I wish to say that a portion of my paper is only what I have written and insisted upon, more than once, previously. However, as I consider the subjects dwelt upon of great importance practically, I do not hesitate, as opportunity offers, to bring them again to your attention.

things to-day is widely recognized—and among our best men—as practically well-nigh impossible. The blood counts in any given case should be made by the same observer; otherwise they do not tally oftentimes. This may arise, unfortunately, from two causes, assuming two observers are equally competent. First, and most frequent, reason is, their apparatus and technique are not often absolutely similar; they can't be identical. Again, men's eyes are not invariably normal; at all events, they don't see straight. As an example of the former in another line of research, I would instance *differences* in *urea estimates* made by two observers who make urinary analyses. These differences I have noted more than once. As an evidence of the second, I would remark that individually I have ceased to try to make my ocular estimate of hemoglobin coincide with that of more than one hospital interne. If I, or he, make reports continuously, it makes really little difference, because comparison is relative between observations made by the same person, same method or technique, same eyes. But with two persons there can be no comparison, and one observer is right and the other is wrong, in reality; but which one is right and which wrong—there is the rub, and who will, who can decide in these moot cases? And surely we are not going to call in a third person to decide ordinary differential blood counts, or urea estimates, or percentage of hemoglobin.

Moreover, unless differential count is made by this third person at the same time as others, it is unsatisfactory because condition of blood may have changed very much during interval between counts. I have had lately just such an experience in a doubtful case of another kind.

In Dr. Smith's valuable paper on the "Essential Nature of Croupous Pneumonia," read at a stated meeting of the New York Academy of Medicine, December 17, 1896, he writes that, if his theory be sustained, "it would follow that the most natural direction for therapeutic effort would be that of attempting to render the exudate inimical to the development of the micrococci. This might be effected," Dr. Smith also writes, "by acting through the blood, but better and more directly by inhalations." The value and proper use of inhalations in the treatment of pneumonia has been insisted upon by more than one prominent practitioner. "Dr. Andrew H. Smith, a few years ago, reported the successful employment of chloroform inhalations in the treatment of pneumonia, and commenting upon this article and a letter on the same subject by E. J. Whitehead, Dr. E. F. Wells of Chicago recalled a report by Baumgartner of 201 cases treated by himself and others with but seven deaths, a mortality of 3.5 per cent. Chloroform inhalations were also commenced by the late Dr. Roberts Bartholow, by Stiff, Theodore Clemens, and others."[3]

The value of creosote by inhalation in vapor has been asserted by myself, and doubtless by others—yet it is ignored by most of the text-books on medicine. To quote from a paper read before this society January 7, 1898: "Some disinfectant vaporized by boiling water may be advantageously generated in the room, both for the possible good to the patient and to prevent the spread of disease. The drug upon which I rely most for this purpose is beechwood creosote. I believe its judicious use is almost always satisfactory. Creosote is easily volatilized; it has undoubted antiseptic power; the odor of its vapors is unobjectionable, harmless, and they frequently arrest cough and bronchial irritation in a remarkable manner." "In case of pneumonia following grip, I can affirm their useful effects in promoting the rapid resolution of the disease. I have also had some reasons to believe that they prevented the transmission of the primary affection, and it might be of the complicating pneumonia. This view is plausible, since we know that thorough disinfection of hospital wards has arrested the spread of pneumonia, when previous to the use of disinfectants the disease showed no tendency to abatement."[4]

"During my service in St. Luke's Hospital during the winter of 1897, several cases of pneumonia were treated partly with creosote internally and partly by inhalation of creosote. These cases, in my judgment and in that of my house staff, were favorably affected by creosote treatment, although we could not carry it out altogether as we desired, from the fact that the patients were treated in the general ward of the hospital."

"I am of the opinion that creosote vaporized and inhaled frequently, almost constantly for several days, is far more beneficial and essential than the same drug when it is given by the mouth."

In a paper read before the American Climatological Association, June 4, 1904, and which was published in *American Journal of the Medical Sciences*, December, 1904, I wrote as follows: "With the first symptoms of chill, fever, pain in the side, cough and expectoration, I believe beechwood creosote should be vaporized more or less continually in the patient's room. I am confident there is no drug used in this way which has more preventive value in the treatment of pneumonia. Of course I cannot prove to others that several times already by this means I have prevented in private practice, as I believe, what otherwise would have become pneumonia. Whether it would have become croupous pneumonia or bronchopneumonia, I am not prepared to say except in a hesitating way, and with, it may be, a conviction tending toward the latter opinion. I wish it to be understood that I only give to creosote a very slight or moderate antiseptic power locally; but I know it is an anticatarrhal agent of great value directly and by elimination through the bronchial mucous membrane. Further, I am thoroughly convinced it is the best way to give creosote so as to obtain its constitutional effects without disturbance of the stomach and, as a rule, without injury to the kidneys. It is wise, of course, if creosote be used freely in inhalations, to examine the urine carefully and frequently for any appreciable amount of albumin. If this be present we should try to determine its cause—whether it be the result of pneumonia or of the action of the creosote, and act accordingly." Occasionally, creosote by inhalation used too freely gives headache to the patient or to the nurse. In this case it should be intermitted for a few hours, perhaps, and the room thoroughly ventilated. It is also my belief that creosote thus used prevents the taking of pneumonia by the nurses in attendance or by any near relative very constantly in the room. "In exceptional cases and in certain epidemics when the pneumococci are more abundant or more virulent, or both, than usual, the transport of the noxa of the disease through the air no doubt occurs, and may be best neutralized primarily by insisting upon having the vapors of creosote in the room." This view is supported by the Chicago Board of Health, and its yearly bulletin already in 1902 stated "that the inhalation of formaldehyde gas will prevent a very large proportion of cases of the diseases which now threaten the public health"—referring especially to pneumonia and influenza. Dr. Frank W. Reilly, Assistant Commissioner of Health, in a personal letter to me, dated February 27, 1905, confirms the

value of statement of Health Bulletin of 1902, and again in 1904. In the Bulletin of 1902, Dr. Reilly describes a formalin box which "should be carried on the person during the day and put under pillow at night." At the onset of symptoms of having "caught cold" begin inhalations, and frequently the cold will be abated. Personally, in view of my own experience, I should prefer using a perforated zinc inhaler with equal parts of beechwood creosote and spirit of chloroform. Some years ago I made frequent use, and in very many cases, of this inhaler and often, I am convinced, I have been very helpful to patients with initial symptoms of cold, *i.e.* sneezing, coughing, running of the nose, etc. If the pneumonia becomes developed, I believe antiseptic mouth washes and creosote inhalations should be continued throughout the acute stage of the disease, and, indeed, until the local consolidations have been resorbed."

The pathogenic organism of lobar pneumonia is admitted to be the pnuemococcus or micrococcus lanceolatus. It is omnipresent and is found, we might say almost constantly, in the secretions of the mouth and throat of seemingly healthy persons. What endows it with special virulence in certain cases we do not know. However tenacious of life this microbe may be under favorable conditions, we know that it is exceedingly vulnerable. In sputum, moist or dry, it preserves its vitality for a long time, but in culture it soon dies. F. C. Wood has shown that when the dried sputum is pulverized the contained pneumococci perish in from one to four hours, even when kept in the dark, and in about one hour when exposed to the sunlight. Given a microbe, which perishes so quickly under adverse conditions, growing in culture in the accessible alveoli of the lungs, it ought to be a comparatively easy matter to arrest its growth. And so it appears to me and to some others who have to deal with the disease in actual practice.[5] Is there not, also, in this important fact a very substantial reason why we should endeavor to employ creosote inhalations early in the treatment of pneumonia, before lung consolidation has taken place, and while we may yet legitimately hope that the antiseptic vapor may reach every portion of the affected pulmonary area? But in order that growth of microbe may be stopped and to place pneumonia in the category of curable diseases, sometimes easily, sometimes with difficulty, *"the time of the treatment* when begun is most important—essential and decisive at times in regard to the outcome of the disease."[1]

"There can be no question that influenza, or grip, is the most important factor of the increase of pneumonia. Influenza[6] is a germ disease and therefore contagious. Where strict isolation has been possible and effected, the disease has seldom appeared. By avoidance of grip many subsequent cases of pneumonia may be prevented. If grip be taken and creosote inhalations be employed properly and soon enough, other cases of pneumonia may, also, be prevented.

The influenza germ has been found by the laboratory experts in pneumonia, and a bacterial examination is therefore of the first importance.* Avoidance[7] of living in close quarters (as many city people do) and of frequent contact with infected persons should be insisted upon to limit the prevalence and fatality of pneumonia. The importance of attention to these rules is in accord with the result of Dr. J. F. Biehn's investigations, "who has demonstrated that, while the individual inoculation of the pneumococcus from a healthy person may be innocuous, the inoculation of the coccus from two or more healthy individuals is unfailingly virulent."[7] The Pneumonia Commission appointed by Dr. Darlington in August, 1904, says "that there is a possibility that pneumococci of greater virulence than those found in the mouth are inhaled with the air current, determining the onset of the disease. The practical point for prevention is the necessity of avoiding all unnecessary contact with a pneumonia patient, and the further necessity, on the part of other members of the family, nurses and attendants, for sterilizing their throats during the course of the disease."

As showing, however, the very notable and yet hitherto at times unexplained variations of mortality of pneumonia in successive years, witness the fact that in Chicago in 1905 "there were 3,586 deaths reported, or 552 fewer than in 1904—a decrease in the 10,000 rate of 4.2 per cent. from the average rate of the previous ten years and of 15.9 per cent. of the previaus year."[8]

"By doing the right thing at the right time, life may be saved; when there is delay in doing the right thing, life may be lost." Put your patient to bed immediately on the advent of serious symptoms of the disease, provide him with the best nurses, begin inhalations of creosote, and use other curative means judiciously, and I believe many even bad cases may be saved. But delay these primary and efficient, though simple, means too long, and the patient will often die. He will die because the poison of the disease has taken hold of him too strongly, in too large quantity, and before proper and suitable means have been employed to check or throttle it. Again, there are some cases of pneumonia, as there are some cases of diphtheria, enteric fever, scarlatina, smallpox, etc., which will almost inevitably die to-day, as always, up to the present time, no matter what treatment is employed. And the proof of it lies in the record of medicine for one hundred years or more. Indeed, the virulency of some of these cases is such as to render them well-nigh hopeless, and they will remain so unless medical science gives us curative sera superior to any we now possess."

"We know to-day that the pneumococcus is found in the secretions of the throat and mouth of many healthy people, and for long periods of time. One or more of the contributive causal conditions may render these microorganisms virulent or infective. Quinsy sore throat, diphtheria, influenza, pneumonia,[9] may proceed therefrom. In the tonsillar crypts may be found not infrequently various septic organisms, "among which staphylococci, streptococci, pneumococci, and leptothrix are abundant." "The mouth is the great highway for receiving germs into the air passages; it is, also, the convenient receptacle for the cultivation of the disease-producing germs. Food accumulated between the teeth and kept at body temperature is a rich soil for pneumonia germs. An unclean mouth will readily furnish material for the destruction of its owner."[7] It is essential, therefore, for every one, so as to aid in the prevention of pneumonia practically, to keep their mouths and throats in a sterile condition as far as possible.[7] "The secretions of the nose, mouth, and throat often teem with the influenza bacillus, and they should be immediately destroyed or thoroughly disinfected. We may not be able to avoid the access of germs which produce pneumonia, but we can in a large measure live and act, so as to rob them of the opportunity to become fatally active." Is it not specially indicated, therefore, to make use

* Bulletin of the Health Department, Chicago, February 10, 1906, states: "The pneumonia mortality is largely affected by the prevalence of influenza. Bacteriological examinations in the laboratory continue to show a marked preponderance of the influenza bacillus."

of antiseptic gargles and mouth-washes frequently when we have reason to fear the possible beginning of pneumonia? This antiseptic mouth-wash, at such times, should have a slight acid reaction, simply because we know that the pneumococcus does not thrive in an acid medium. Dr. S. Lejan,[10] who is very strict as regards the observance of using mouth-washes, "enjoins in every case strict buccal antisepsis, by rinsing the mouth frequently with solutions of boric acid (4: 1,000) or of thymol (1: 1,000). It is indicated, also, to continue the use of these antiseptic gargles and mouth-washes even after the pneumonia is recovered from, as pneumococci may still remain in the mouth and may possibly occasion a recurrence of the pneumonia in the individual."[11] It is claimed by Musser that a dose of calomel, if sufficiently large and employed properly, may act as a local disinfectant of mouth and throat, and later, in like manner, in stomach and bowels.

Incidentally, and finally, I would add that on account of the deleterious action upon the teeth, I do not approve of a mouth-wash of acid reaction to be used habitually in a condition of normal health.

"In more than one instance in the treatment of pneumonia, and where other heart stimulants had been of little or no avail, I am sure I have been of use and helped save life with the use of the best available preparation of coca. Given by the mouth or hypodermically, it has often been of service when I had almost given up hope. The reason, I believe, that this agent does not more frequently respond to our wishes is because the preparation employed is relatively inert. Many coca leaves, not to say the far greater majority, are dry and of poor quality when first gathered. Further, the wrong variety of leaf from which to obtain the tonic alkaloid of the plant is usually employed. Hence, much of the coca used, as wine or extract, contains a large percentage of cocaine, which I believe has little or no tonic properties, and does not contain the other derivatives most valuable in cardiac exhaustion of pneumonia."[1] "Further, the coca leaf does not bear transportation from its native soil after being gathered, and if this is done the tonic alkaloids which it contains become changed and worthless medicinally as a nerve tonic."[12]

"For these reasons, must unfortunately, if we wish to give our patients the benefit derived from coca, we are obliged to recur to the use of one or other of proprietary preparations. I should not advise, with my present acquired knowledge, the continued use of coca in the treatment of pneumonia. It is more particularly as a temporary help when, however, help is most needed and sought for, that it should be used. Under these circumstances neither alcohol, ammonia, strychnine, nitroglycerin, digitalis, nor any other drug will be so soon and so distinctly valuable as coca."

"In those instances where small, frequent, irregular and rapidly-failing pulse and very weak heart follow closely upon the acute general phenomena of pneumonia, the best preparations of coca are sometimes simply invaluable."

So far back as 1894, in a paper read before the Association of American Physicians,[13] on the treatment of croupous pneumonia, I wrote as follows: "On several occasions already, when a patient's condition has seemed desperate, and after strychnine to the highest possible limit compatible with safety had been vainly employed, I have had at least temporary results of considerable value from the use of hypodermic injections of extract of coca, made up aseptically. I am of the opinion, however, that we must rely also in these cases upon the use of nitroglycerin hypodermically in sufficient doses to restore the patient to a relatively good condition. These hypodermic injections, alternated with those of strychnine, will do what no other drugs in my experience will accomplish."

As an instance of the value of coca, even when given solely by the mouth, where there was extreme weakness following the acute symptoms of double pneumonia and where the best brandy was gradually failing to hold the patient's heart, I would offer the following case observed latterly in Dr. Geo. A. Spalding's service at St. Luke's Hospital. Incidently, I would add that the patient referred to was a former patient of Dr. W. M. Tompkins and of myself, and was sent to St. Luke's by us. I followed up the patient pretty closely after entrance in St. Luke's, and it was I who sent *old brandy* and *coca* (fluid extract) which helped very materially to save her life.

Case.—S. McL., widow, Irish, 57 years old, scrub woman, entered St. Luke's Hospital November 14, 1905. I take what follows from history of case kindly given me by Dr. G. B. Capito, house physician of Dr. Spalding.

"For last five weeks patient has been feeling out of sorts and has had slight cough. Yesterday, was taken with severe pain in right shoulder and down right side. Pain is severe, sharp, worse on breathing and moving body—was nauseated and vomited at first; had chilly sensations, but no fever. Pulse regular, full, bounding. Apex beat of heart not visible nor palpable—action regular—second sound accentuated.

Lungs: Right, dullness from spine to base; diminished breath sounds; a few crepitant râles, fremitus present.

Left: few crepitant râles at left base.

November 15. Right Lung: Dullness from fourth interspace to base, bronchial voice and breathing, numerous subcrepitant râles, fremitus increased.

November 20. Left Lung: Dullness, bronchial voice and breathing at angle of scapula, numerous crepitant râles.

November 25. Bronchial breathing less intense, numerous moist râles over both chests posteriorly. Leucocytosis varied from 10 to 25,000 during eight days.

Treatment: Mustard paste locally. Internally, strychnine, digitalis, old brandy (the very best), and finally, when these seemed to fail, *fluid extract of coca,* begun on November 26, fourteenth day of disease. At that date, temperature 98½°, respiration 30, pulse 100, but the patient appears *very weak.* Patient left hospital completely cured two or three weeks later.

"It is wisdom to give black coffee frequently in advanced cases of pneumonia with evidence of heart weakness or cardiac degeneration, whenever our coca is unreliable, either by mouth or rectum."[12]

In the treatment of pneumonia we should bear in mind constantly two facts most important. First, the outcome of the disease is a question of the vital resistance of the patient; whether or not he can stand the storm until the critical time when the morbific processes reach their maximum of development. This means the *crisis,* which, however, with old people frequently does *not* occur, at least in such clear-cut manner as often described. Still there is at a given period a waning of the poison of the disease (lysis) sometimes with young or middle-aged adults, more frequently with old people. It is during this period that the best old brandy and coca are especially required during many days.

Again, in the second place, we should remember

that in many cases the virulence of the disease is not due to the amount of lung tissue involved, but to the degree of the toxic influence of the pneumococcus on the general system. If the toxemia is profound and progressive, the culmination is death, and we have no means as yet to neutralize it. But if the toxemia be moderate and not progressive, may we not hope that in some of these cases if we make use of creosote inhalations from the beginning and throughout the pneumonia, and bring in use our old brandy and coca, in suitable doses and at the proper time, we shall save many patients who now die, as I believe, because of lack of proper judgment and absolute insistence upon doing certain primary things at the right time. Whether or not, coca could be given with advantage from the inception of the attack until its termination, I do not know. It may be that it could. And yet possibility of harm has prevented my using it continuously hitherto. I leave this with the society to decide.

In view of the remarkable success achieved latterly in the treatment of pneumonia by the tent treatment at Fordham Hospital by Dr. B. F. Dunn, and of roof treatment (out-door), at the Presbyterian by Dr. W. P. Northrup, permit me to speak for a moment of what is already known and has been often insisted upon. The importance of a large, thoroughly well ventilated room with open fireplace, as being essential in the treatment of pneumonia, has been urged more than once by myself and others. Indeed, the lack of these conditions is one of the strongest reasons for inveighing against the actual treatment of pneumonia cases in hospital wards, and explains in a measure how it is that our successful treatment in these institutions is not comparable with what we may and do obtain in private practice, so long as the old order of things continues wrongly to be perpetuated. When I make use of creosote inhalations, I also insist upon perfect ventilation, and frequently, and at more or less stated intervals, I stop inhalations altogether, and open the windows widely. Of course draughts must not be tolerated, and windows are opened more or less, according to temperature, moisture, and what I regard as being, and have for several years, considered to be, other essential requirements of the patient's judicious treatment. The patient affected with pneumonia needs, of course, plenty of fresh air continually, and this should always be amply renewed before becoming stale or injurious, by reason of "unnecessary breathing of the air from the patient's lungs" (Loc. cit.).

On the other hand, we should not be "unduly enthusiastic" as yet, about one agent and one alone. Outdoor treatment, tent treatment, may be proven later, with a larger number of cases, to be a *sine qua non*, not only in treatment of pneumonia, but also in treatment of acute bronchitis, influenza, and other respiratory disorders—Festina lente. The indications are there, it is true, but the thing itself is not absolutely proven yet a while, and radicalism in medicine, I believe, does almost as much harm as pure, unalloyed ignorance. Up to date it seems to me probable that "the most useful single agent in the treatment of pneumonia, as preventive and curative, is creosote, used preferably, as I believe, in inhalations, properly given and continued for a sufficient length of time."[14] And this judgment I hold, not only in view of my own experience of many years, but also because of that of several eminent clinicians.

Note.—Since this paper was read I have received communications from Dr. John G. Curtis, Professor of Physiology at the College of Physicians and Surgeons, New York, and from Dr. S. Solis-Cohen of Philadelphia, so well and widely known as a medical writer and practitioner. Dr. Curtis writes: "It is hardly conceivable that vapors should fail to reach the alveoli, and to be absorbed by the blood thence." Dr. Cohen writes: "My own impression is that they (vapors) do reach the air-cells."—B. R.

SYNTHETICAL MEDICINE.

By EUGENE COLEMAN SAVIDGE, M.D.,
NEW YORK.

This original subject suggests the following questions: 1. Is any field of medicine uncovered? 2. If so, is this field important? 3. Given an uncovered field of importance, is the process suggested therefore (*a*) definite; (*b*) legitimate; (*c*) generally available, and (*d*) productive of results?

If these questions can be affirmed, the subject is of value to the profession. I believe they can be affirmed.

Being new, the subject must be explained before it can be discussed. A published definition by the writer will serve as a starting point for the thesis.[1]

"Synthetical Medicine tentatively so called by the writer, is a field almost virgin to the profession. . . . It is as distinctive in domain as Preventive Medicine. Preventive Medicine includes all the comprehensive measures of hygiene, vaccination, antisepsis, quarantine, and military medical supervision—now focused to as fine a point as shooting a soldier on campaign who drinks unapproved water—which have conserved human life everywhere to figures beyond computation. A return to the conditions of a century ago would bring an appalling rise in mortality. Yet the work is nearly all recent.

"Synthetical Medicine, on the other hand, deals with the individual instead of the community. It is restricted to those who are self-guiding and provident, who study to get the best from their brain-pan full of protoplasm; it is hopeless with the rabble. It assumes to recognize and postpone that eventual trouble, be it in heart, liver, kidney, or blood-vessel, which a grouping and study of present conditions will often show years before it takes its classified text-book form. That this can be done by capable medical men is my most earnest conviction. If so, the immense importance of the subject to community medical economics and life insurance is at once apparent. Study the necrology of the last decade, even in this one country, and consider what an average of five years more to each of these elect of civilization would have meant for the family, community, and race. A man like Pasteur is more valuable to France than many regiments of soldiers.

"Synthetical Medicine, therefore, saving the waste of the most valuable kind of life—the lives of those who are contributing to their age—should yield the highest medical rewards of the future and

restore to medical men the revenue robbed from them by their own success in Preventive Medicine."

"Assuming to recognize and postpone the eventual trouble," however, is a restricted and incomplete statement regarding this new process, tentatively named. Its further assumption is to answer the question, "What in addition to the text-book diagnosis has the patient?" Frequently, as I shall try to show, the *unclassified* troubles are of more import to the patient than this text-book diagnosis under which he is classified. This question, therefore, invites along other avenues of help to the patient. A synthetical process is one that builds from many concrete conditions an entity, which may differ in order from any of its component parts as widely as a cow differs from its pasture. This entity, this new generalization, if not found in medical text-books, belongs to the realm of "The Unclassified Troubles," to which the writer has devoted a paper.[2]

Classification is necessary in every science. But as the first sprout of green above the ground may require time and development before it can be assigned to its family, so in medicine there are innumerable unclassified first signs discernible long before any of them have developed sufficiently to be ranged under their definite classification.

Synthetical Medicine assumes, in addition, a utility in this field of unclassified first signs.

Simply to mention the field, therefore, the very terms of the criticism thereon—that it is uncoverable—is to affirm that it is uncovered. The writer has succeeded measurably in classifying this unclassified, and reducing the process to a semblance of a science.

Its success has been too uniform to be coincidence or special skill. The process is the point; and believing this, the way has been paved in previous writings for the hazardous publication of the new process as a contribution to the profession.

This paper will not deal with therapeutics, but will try to point out the conditions which are at present neglected; neglected at cost of life; which conditions science can modify; which life science can save. Obviously, if these modifiable conditions are not seen or understood, remedial suggestion therefor is impossible. The criticism, "You imagine these things," must be met with the retort, "You do not see them."

The thesis, being synthetical, must start with simple declarative statements, few of which will be seriously disputed by the profession.

If one kidney is removed, an autopsy years later will show hypertrophy of the remaining kidney. There has been manufacture of new kidney substance by increase of function. That increase of function will make new capacity in most departments of the human organism, is obvious on scrutiny. (The degeneration from over-hypertrophy is another subject.) The superskill of remaining sense in the blind, the deaf, the mute—in their touch reading, lip reading, and intensified remaining powers—is not simply a burst of compensatory generosity from Providence, but from the law that an increase of a function will widen its capacity.

"Every schoolboy knows" that with proper activity he can swell his biceps, hypertrophy his heart, increase his chest expansion, *i.e.* manufacture new lung tissue. The physical supremacy of the present generation of Americans over the last proves that, while by thought a man cannot add an instant cubit to his stature, by forethought he may add several. Almost as demonstrable is the improvement of nutrition of the motor centers around the fissure of Rolando, by volitional (not reflex) motor impulses under athletic training.[3]

One has but to mention the subject of exalted special sense by unusual training—from the piano tuner to the tea taster. Little girls in India, born to the business of selecting different colored yarns for woven fabrics, are able to discern dozens of shades which show no difference to us. Freak balancing of the vaudeville, coordinating to write with the feet, juggling, even the muscle-swelling Sandow, self-upbuilt from a weakling, all show a lesson of possibility to us of more sober profession.

Not alone then are kidney, heart, lungs, biceps, and brain cortex capable of having additional substance manufactured for them by properly directed function; not alone can extra capacities be given in the special senses, as in the compensatory superskills, but every other tissue which is the product of life is capable of self-increase under certain conditions. As well-known examples, consider the extra length of the intestines of the Russian peasants from their bulky, innutritious food; or the enlargement of the prostate; or the broad hips of Holland women, developed from a conception of their beauty, which leads these women even to wear bags of sand to simulate the hips, if nature has withheld; or the gluteal development of horses in hilly regions; or the varicosities around the nose-wings and cheek-bones of those who have made this increase of capillary caliber by continually dilating their surface blood vessels with alcohol; or those newly manufactured vein calibers when collateral circulation is established—naturally in nature's efforts at self-redemption, or artificially, as by surgery in cirrhosis of the liver, or in decapsulation of the kidney. The blood itself, which is the practical basis of life, is not only measurably changeable in richness of component parts—these measures are daily routine—but more, is susceptible of relative and absolute increase in weight, as in those cases of obesity referred to later.

This capacity in the human organism for self-increase, for self-improvement as well as self-destruction, is one of the secrets at the basis of Synthetical Medicine.

The Incipient Dwindling of Function.—There is corresponding capacity in the human organism for atrophy and dwindling. Kidney, heart, lung, brain cortex, intestine length, surface capillary, blood volume and richness, each and all can be lessened under certain conditions. The prompt recognition of this incipient dwindling of function is another basal secret of Synthetical Medicine.

Is it necessary to mention the atrophies? Consider the small contracted kidney of anxiety—the Wall street kidney; take the sempstress's heart, lungs, biceps—of wet tissue-paper thickness; take the flat head of the Indian from burden bearing; the dwarfed feet of the Chinese woman; the withered area of ring or truss pressure on an otherwise healthy body; or the shrinking of leg muscles from even two weeks in bed.

As for brain atrophy[4]—the conceded early mental decay of the agricultural classes, from lack of circulation in the brain, has been advanced by thoughtful men as really the cause of death in a large proportion of the population. Our death certificates frequently charge the kidney, the liver, the heart, or the arteries with the death-cause which really rested in the slowly atrophying brain. The formula might be thus expressed: (1) brain sloth, leading to gradual disuse of functions; (2) from which comes atrophy of the parenchymatous cells all over the body, curtailing their selective duty of taking up nutrition and life-waste from the blood; (3) from this results a diminished resistance to an increased amount of self-poisoning; (4) liberation of an army of protecting leucocytes, which throw

up their fortresses (like hard tissue around a boil) in a reactive thickening all through the lumen of the arteries, arterioles, and surface capillaries. Fibrous tissue, the scar of this formula, thus takes the place of selective cell tissue, and slowly contracts and starves the individual from without inward.

What difference which organ gives out first; whether we say Bright's disease, cirrhosis, or endarteritis if the cause starting the insidious formula is in the brain—and note well, in such non-material elements as a loss of interest, a discouragement of motive, a resignation to a supposed inevitable; *i.e.* in a sluggish cerebral circulation? (The superactivity of cerebral quality is another subject.)

Elsewhere the writer has devoted a paper to show the extent to which the brain may be considered the source of vitality.

It will then be admitted that various organs and functions of the body are susceptible of increasings and dwindlings. Were the scientist able to command conditions, like a master at the organ keyboard, he could bring out this note and that from the complex mechanism—increasing here, suppressing there—making a synthesis in medicine like a harmony in music. Luther Burbank, in California, by a similar synthesis in plant life is building up wonderful new creations. The dwarf trees of Japan and the big trees of California speak by contrast of environment possibilities in the vegetable kingdom. Many of these conditions are commandable by the Synthetical physician, and applicable to the human organism.

If "the individual withers," therefore, he may be made to do so advantageously in departments of our own selection: notably in the capacity of his large intestine, his venous system, in the deposits along the line of his blood vessels, *i.e.* his connective tissue formations and in his tendency to obesity.

In this last direction it is quite feasible to reduce by a large fraction the territory to which blood must be pumped by the heart; to increase by like proportions the relative and absolute quantity and quality of the blood and the muscular power of the heart; to reduce connective-tissue formation; to increase parenchymatous tissue formation.

All the hypertrophies, all atrophies, are mixed in blessing and the reverse. It is their proper synthesis—like the individual elements of the state of wisdom, to which all subscribe but so few apply as a whole—that is the loud-calling opportunity of the medical profession.

Metchnikoff has recently popularized his results of a scientific study of age. He has shown, for example, that the graying of the hair is from the abstraction of the pigment by phagocytes. He signals the superabundant bacterial flora of the large intestine—with which fecal storage house he cites a case to prove we could dispense—as the trouble-breeding place. Here is a field we should reduce. The bacteria bring out the leucocytes, and the leucocytes throw up their fortresses after the formula given above.

But we cannot send out a protecting army, even of leucocytes, without feeding them, or, as Metchnikoff puts it, they will turn and devour their own populace. And this is precisely what happens. The repelling army is called out in excess of the body's power of commissariat, and it feeds off the organism, whence the pallor, the disappearance of pigment, hemoglobin, and red blood corpuscles. The formula here might be put: (1) the more bacteria; (2) the more leucocytes; (3) the greater consumption of pigment, hemoglobin, and red blood corpuscles; (4) the greater production of connective tissue; (5) the greater reduction of nutrition for parenchyma, and the greater failure of excretory selection. Nourishment needed for repair, and even for the organism itself, is consumed to repel, like burning the bulwarks to keep the engines going.

Not only then should the large intestine be diminished, but the gradual distention of the caliber of the venous system should be checked. This over-distended condition of veins takes from the whole quantity of blood an undue share, to be kept therein as sluggish, sewerage blood. Even a youth, passing from the carbon-laden air of a badly-ventilated crowd to fresh ozone, realizes instantly the vitalization from bright arterial blood. How much more important is arterial capacity and vein tonicity to the aging, blue-appearing individual, who has no disease, who but thinks he is getting old and tired, when he is principally being stifled with his own sewerage? Less intestine, less venous capacity, less fibrous tissue; more arterial resilliency and surface.

Then there is the adjustment of the heart to its increasing work throughout the body, as the calibers close in and as obesity grows. Consider a moment the statics of the circulation. Note the extra burden on the circulation of a pregnant woman or of a woman carrying a fibroid; or that produced by an Esmarck rubber bandage wound tightly around a leg. Note the static disturbance after the amputation of a leg, in the increased susceptibility to apoplexy, hemorrhage. Add the weight of a leg, or of a gravid womb, or of a fibroid to any pendulous abdomen in the form of fat; or contract your surface calibers, as cold does, or as malaria does during the chill, when the surface is deserted and the central organs are overfilled, and you have similar static differences. Every man whose arteriole calibers are closing in—*the first insidious dwindling of caliber*—is daily loading a growing burden on his heart pump. The relation of fat to ovary, thyroid, circulation, elimination, and vitality, is brightly signaled to us every time some unsuspecting patient drops dead from heart failure—whose only symptom was some increasing weight and shortness of wind.

Almost every other man and woman over thirty carries, not a marshal's baton in his knapsack, but death-warrant in his pendulous abdomen. I have called this triangular figure in women—with base below running to an apex above—the "apical" or "the Queen Victoria figure" (meaning no disrespect to her whose figure all know; who yet despite it, from fullness of other activities, lived to surplus decades of usefulness). This "apical" figure is an unneeded burden on heart and excretory functions, which can be absolutely lessened. I speak so surely here because routine success therein for years has made it necessary to struggle against the epithet of obesity specialist.

Hence, by increasing, by diminishing, by developing, by suppressing—*by not leaving to accident*—Synthetical Medicine may, for example, safely carry an individual who has no present disease through next winter's pneumonia; or save him from that pneumonia, which is thus easily grappled in its preventable stages, though cured with difficulty when entered upon.

The indulgent criticism that "we recognize and do all this" may be true individually in the case of our greatest men. But the writer has not seen this field definitely crystallized and deposited in type for reference, as a focused entity. And while priority is a pleasing fact, it is only of importance to the claimant; the point is to give handle to something of value.

For this important uncovered field of medicine the writer is able to suggest, *in conjunction with all the usual resources of medicine and surgery,* certain definite, legitimate, available, and productive processes. He feels justified in claiming that the profession can (*a*) "recognize and postpone the eventual trouble"; (*b*) that it can receive new light on the collateral, unclassified troubles, to which the text-book diagnosis may be entirely subordinate; (*c*) that it can thereby rescue from charlatanism the field of its own present failure: the chronic, "run-down" cases, coming under no text-book head; (*d*) that it can enter a new domain wherein lies savable life, at the time of life's greatest value; a domain at present unwritten, in which knowledge and purpose can modify by a readjustment of forces.

Avoiding discussion of remedial agencies until the opportunities calling therefor are well exploited, let us study an extended example of possibilities.

Age will be "the eventual trouble" in every person living to reach it. Its psychology is worthy of study. For purposes of illustration, I divide it arbitrarily, with specific restriction of term, into states of (*a*) undue resignation, (*b*) rebellion, (*c*) proper functional adjustment.

The vast majority are unduly resigned. Men slowly subside into their untidiness, old stories, and melancholia; women into an apical figure of querulousness and constipation. The picture of an old man dodging a horse in crossing the street will illustrate. Drivers do not fear the boys so much; their reflexes are keen, they act quickly and truly. But the old man's reflexes are slow. In his undue resignation to a supposed inevitable, he has brought nothing new to bear upon his susceptibilities; his reflexes are therefore dull, partly from disuse, partly from the hardening changes of self-poisoning, and partly from the natural processes of dissolution. Most of his accessory faculties have dwindled. His routines remain, but they have been adjusted to the line of least resistance. His back is bent, his step is shortened, so that even these routines are brought as near disuse as possible.

How much of this is natural dissolution? How much is from a desiccating brain and the consequent atrophy of disuse and self-poisoning? The latter element, with all of its nutritional effects, can be placed absolutely under control.

Suppose, for example, like the community at Oberammergau who live the Passion Play, another community lived day and night another play; and in that play a youth acted the part of a paretic, a tabetic, or a senile infirm. In how many months of the assumed paretic, tabetic, or senile quality, continually lived, day and night, could we find the first acquired atrophy? We should have here the "synthetical pathology," so to speak, of atrophies and self-poisonings acquired through a conception of a part, just as we see daily examples in shoemakers, tailors, and others, with occupation neuroses.

Actually among us, however, we can see in a group of tabetics a marked family resemblance in characteristics, quite apart from their spinal lesion. In all will be noted certain atrophies—like the physiognomy of a cripple—many of which result from abandon to the conceded hopeless nature of their trouble. The name, *tabes,* or wasting, tells the former conception of the trouble, as a failure of nutrition. The sequence is now better understood, somewhat after the following formula: (*a*) a toxemia, (*b*) a leucocytosis, (*c*) a sclerosis and obliteration of arteriole caliber, and (*d*) as the final and not first cause, a failure of nutrition. Probably the accompanying disablement contributes as much as anything to the advance of the disease itself. Frankel—with splendid results according to patients who have taken his regime and lived with coafflicted in Switzerland—has used this truth in his treatment of locomotor ataxia by starting early to teach collateral movements and new coordinations. This obviously develops these new motor tracts, just as the motor areas in the brain around the fissure of Rolando are nourished and developed by voluntary (not reflex) muscular action.

Frankel may accordingly be said to be practising synthetical medicine in this special "classified" domain, in that he is rescuing these collateral atrophies by training—even conceding the hopeless nature of the already degenerated nerve fibers. The point is not the method of treatment, but the illustration it affords of synthetical methods. The Russell committee at the Post-Graduate Hospital, the new Columbia College committee, are practising synthetical methods on the special classified trouble of tuberculosis. Edebohls, rescuing a starved-out kidney by laying new conduits of blood to the parenchyma, is practising synthetical medicine with a knife upon a special organ. So with the new surgical method for cirrhosis of the liver. Modern dentistry, however, is the best understood adaptation of this foreseeing process in a local field. Even the laity foresee, and thereby get "surplus decades" for the teeth.

In identical manner everything that is lost by undue resignation can be rescued by the purpose and knowledge of the synthetist. In all these departments his rôle is to adjust the disharmonies between hypertrophies and atrophies.

On the other hand, consider the rebellion—in the specifically restricted sense here used—of the old man, or the old woman, with alcohol, drug, or perversion. Even leaving the moralities aside, and speaking as economist, reckless rebellion conduces even less to *effective* longevity than undue resignation.

Senility has so long been associated in the popular mind with sex decay that the word has acquired almost a shamefaced meaning. The old men whom it is necessary to watch have, perhaps, never realized that there is an erectile quality of the brain, as well as liver, spleen, kidneys, and reproductive organs.[5] Indeed, the term "hemorrhoid of the brain" might well be applied to that condition of persistent thought in diminished resiliency of the cerebral circulation. Blood is engorged in certain parts of the brain, voluntarily in concentrated thought, involuntarily by uncontrollable emotion. The grand old men of history are those who have kept this cerebral erectility and the prompt distribution of the engorged blood well under control. Those under this rebellious heading may be said to have a "hemorrhoid of the brain," keeping them at this futile sensation hunt, with drug, alcohol, or perversion, which sometimes nullifies a whole career and brings sorrow upon a family.

This condition is largely the result of a disharmony in the application of a wrong function to a right call, under the misconception that one should follow the same lines at twenty, forty, and sixty. This question most obviously is within the province and duty of the synthetist.

From the sad picture of undue resignation, or this special rebellion, view the picture of proper functional adjustment. These have kept their psychical area unimpaired; they have hope, purpose, utility; they have not allowed their susceptibilities to dwindle. Take a few names from the list: Pope Leo, Gladstone, Moltke, Thiers, Pas-

teur, Virchow, Huxley, Darwin, Spencer, O. W. Holmes, and others even more in point. Has it not been from the fullness and roundness of function—not the contraction—that such men, who "live at the expense of their heirs," reach out into the surplus decades?

If such were originally endowed with special vitality, and are therefore nature's playful exceptions like those attaining enormous stature, their examples may not clarify synthetical medicine. But if *part* of their secret lay in environment, perception, intent, or will, that part of it we can annex. Herbert Spencer was a weakling, yet he completed his synthetical philosophy. Pasteur gave his life's work to the world after his stroke of paralysis. Theodore Roosevelt was too frail a lad for the East, yet something—some entity, physical or mental, plus environment—enabled him to become the strenuous symbol. What part of that entity can synthetical medicine annex? Surely it was not a physical something in the weak ones. On the contrary, it was a knowledge, or a hope with a purpose, which was focused synthetically on their mental and physical organism. It was neither materia medica, gymnasium, nor psychology—but a combination, a foreseeing preparation, a synthesis. Therefore, by a synthesis men have carried feeble bodies to surplus decades of use and happiness. We seek to annex their process.

A knowledge, a hope, a purpose, and environment—these we can as surely annex as any other entity used in medicine. This knowledge of possibility makes hope, the manufactured hope makes effort, and the effort makes result. A condemned man with a short time to live limits his project. Limiting the project stops achievement. Extending the time invites the project, and something results. All that surplus which grows from the directed effort is the harvest of synthetical medicine.

Practically, at the first sign of dwindling we can get light by asking of a man: Has he stopped doing new things, making new journeys, adding new acquirements, reading new books, essaying new leisure habits? Does he shorten his step, bend his back, become shabby in his person, and dwell upon the thought that "youth is a blunder, manhood a struggle, and age a regret?" Has he decreed that his time is short, his faculties (which he weakens by neglect) are failing, and his hope futile? To such an one, unrescued, the popular misconstruction of Dr. Osler's now famous pleasantry—that man is useless after forty—amounts almost to a death warrant.

Can he be gotten to do all these new things? Can you point out to him this hypertrophy, that atrophy, this abandoned susceptibility, that blunted reflex, this rescuable collateral circulation of motor tract? If so, Synthetical Medicine has surplus decades for him—more or less according to earliness.

But it is too late to start the processes when his centers are completely atrophied, his surface circulation entirely obliterated, the cortex of his brain hardened and shrunken; and death has already struck from the surface inward.

Compare two women, and note the life waste which could be rescued. Take one in the late thirties and early forties, of a class spread widely over America. She has neglected her teeth and her musculature; has become "apical," with a rumbling burden of intestines and overdistended veins below her belt. Her heart is flabby, and she is well into Bright's disease before even her specimen has reached the laboratory, and her picture is one of undue resignation and passing utility.[6] Perhaps she has even had dentistry, and secured the "surplus decades" for her teeth, but has neglected all other previsions and provisions as readily available.

Contrast her with another type of woman growing more numerous, as various threads of Synthetical Medicine are becoming better known. Well groomed at sixty, with musculature and sewerage perfect, her interests are keen, her utility and happiness unimpaired. There was a time in the career of the first woman when she could have been rescued for the "surplus decades" enjoyed by the second.

So that we must begin early. Who must begin early? Not the physical culturists of the magazine advertisement, though they undoubtedly have had their true successes. Not the "New Thoughter," or Christian Scientist, though they unquestionably have seen ailing patients, filled with enthusiasm, increase an activity theretofore abandoned. (We know, as they ignore, the material process by which an enthusiasm caught from a fakir's assurance, can light a hope, stimulate an activity, stop a toxin, establish a collateral circulation, and improve a condition down to the very neuron, where a drug might fail.) Nor yet the expert alone at materia medica; for therapeutics limited to drug or knife effects on the human organism can rarely warm the desiccating brain. Not the pedagogue; nor the literateur; nor the laboratory scientist; but the medical practitioner who has lived around his own circumference.

Most especially disqualified is the religious instructor, trained to despise the flesh, "count not this life," and "press forward" to the goal of a future life. "If an eye offend thee—if an arm—" in its letter is the antithesis of the medical viewpoint. This must be even the more emphasized, considering the almost sacerdotal quality of some of the work.

Civilization yearly postpones man's entrance into qualified struggle for ways and means; other animals early scratch and graze. The preparation and the ardor of accomplishment compass the span of activities in most men; they have no surplus decades. Because useless in ways-and-means problems, they have allowed to dwindle the only qualities of use to them in their surplus decades. And of such the question: "Shall a man live hereafter?" must be met by the response, "Does he live here?"

This is typical of those of a first generation who succeed, and come to the metropolis, and then furnish so many examples of cerebral bankruptcy. Trying to adjust material quenchings to inherited spiritual calls for function has, I believe, brought paresis to many a man living in similar disharmony. Consequently, symmetry of function has wider scope than mere skeletal muscle development, or emotional, or even spiritual enthusiasms. This is work for the medical man that no one else can do.

Synthetical medicine reasons backwards from old age thus: If so much of what is thought to be inevitable is really an allowed self-poisoning—considered inevitable, hence not studied or fought—if the legitimate processes of dissolution are but a fraction of the allowed and accepted result, how much of the trouble in all the other diseases and disqualifications is likewise *allowed*, and likewise removable?

As the symptoms of nearly all the diseases—what popularly seems to be the diseases themselves—are really beneficently intended reactions to conquer poison, the resemblance to the aging process is well marked. Inflammation, the congestions, the hurrying forward of new blood, even fever, all are recognized now as of such beneficent intent. In nearly every disease in the textbook, therefore, a

process parallel with the aging process will show a corresponding opportunity for synthetical medicine.

Synthetical medicine can accordingly grow new kidney substance, reduce the area to be supplied by the heart pump, enhance the richness of the product pumped by the heart, increase the muscular tonicity of the pump itself; create new lung tissue, new skin activities, new surface arterioles, new parenchymatous tissue, new circulation in a desiccating brain. Through surgery it can lay new conduits for nourishing blood to liver and kidney when the old are rusted out. It can foretell the atrophy of abandoned function, rescue fading susceptibilities, restrain hypertrophies, and plan for a source of vitality in the surplus decades. It is thus able to postpone that premature death of a man's periphery by the closing of his nutritive vessels, which slowly starve him from without inward.

Again the critic, who indulgently disposes of the subject, may say that all this means simply "keeping in condition." He may dismiss a patient showing no visible lesion, no laboratory finding, with the verdict that "heart, lungs, liver, kidney, reflexes are all right;" he may even find a classified trouble and work on that, and yet miss his full opportunity, and be outstripped in result by one versed in Synthetical Medicine.

This work is of high quality. It should have the best brain of the country, which business now attracts. Except in special cases, it will be but a dream of the profession unless the field is recognized as a special one, in which the usual consultation fee basis does not obtain. The "retainer fee" idea of the lawyer may have to be borrowed. Otherwise the men capable of the work will not turn from their engrossing and more profitable field of "classified troubles."

But Synthetical Medicine can cover a field wherein is effective human life of the best kind. This life is not savable by knife or drug alone, yet it is undeniably savable.

3. Volitional motor impulses, directed from a higher center, should not be confused with the automatic movements of routine, which proceed from the spinal cord. The exercise of the laborer is routine, along the line of least resistance, effacing not breeding energy, and differs in results from the exercise of training. "One goes down one's own stairs with his spinal cord. There is neither reason nor memory in this automatic reflex. A strange staircase, requiring perception, is therefore a tonic, because an exercise of a higher center than the spinal cord,—bringing into action the part of the being where lies the source of vitality." (From the writer's paper in the Medical Record, March 18, 1905).
4. Perhaps no more striking example of cerebral atrophy from disuse will ever be shown the world than by the autopsies on three boys recently executed. Three young men, born of the same mother, living under the same environment, were put to death at the same moment—in expiation of crime. The autopsy showed the brain of the elder, still a young man, markedly atrophied; the next less so; while the youngest, nearer to his original endowment, having spent less time in brain sloth, showed almost a normal brain. The atrophy of the eldest brain, a little later in life, had it been externally visible, would have masked itself to the community as a process of age; it was, on the contrary, simply a disuse and neglect.
5. In . . . the writer called attention to the erectile quality of liver, spleen, and pelvic organs. Recent experiments with the encometer (W. H. Thomson, Medical Record, May 6, 1903), have proven how rapidly the kidneys "can increase and then shrink in bulk by alterations in their circulation—being so liberally supplied with vasoconstrictors and vasodilators that they might almost be termed erectile organs."
6. Long before the laboratory will show kidney disturbance there is a renal physiognomy which is unmistakable to those trained to hunt for it. Like a family resemblance, unmistakable yet too subtle for words, the perceptions of the diagnostician's mind outrun his powers of expression. There is danger, however, in "recognizing" a condition unprovable in a medicolegal view, as this might open wide a door of fraud. See the author's pages in the *Boston Medical and Surgical Journal*, December 21, 1905.

THE HIPPOCRATIC ERA IN MEDICINE.*

By RICHARD COLE NEWTON, M.D.,
MONTCLAIR, N. J.

To one small people it was given to create the principle of progress. That people was the Greek. Except the blind forces of Nature, nothing moves in this world which is not Greek in its origin. So wrote Sir Henry Sumner Maine.

Francis Galton says, "The average ability of the Athenian race is, on the lowest possible estimate, nearly two grades higher than our own—that is, about as much as our race (the English?) is above that of the African negro.

While these statements are quite frequently acknowledged to be true, and while the words of Mr. Gladstone that "the ancient Greek brain represented the high-water mark of human intellect from which the tide is now steadily receding" are also undisputed, the debt that the world owes the Greeks as the founders of medical science is not so generally appreciated. Nor is the remarkable degree of perfection which the theory and practice of physic had attained four centuries before Christ by any means generally understood at the present day.

Prof. Gomperz in his philosophical work "Greek Thinkers" has laid before us the status of medical learning and practice in the days of Hippocrates, and has, with rare acumen and great learning, afforded an insight into the actual condition of medical matters at that remote period which is truly inspiring. Not only has he marshalled his facts with logical accuracy, but with the unerring insight of the true historian,—he has drawn from them inferences of wide application, and has shown from whence sprung much of the truth and error that have characterized medical teaching for centuries and have left their impress on the medical thought of to-day.

He says the threads that bind antiquity with modern times lie open to view, and our present inquiry will have to take them in account. He quotes Herodotus as ascribing the supremacy of the Greek intellect to the fact that Hellas "enjoys by far the best tempered climate," evidently, we might say in passing, a premature deduction inasmuch as with no appreciable change, that we were aware of, in its climatic conditions Hellas no longer produces even a high grade of contemporary intellect.

Prof. Gomperz attributes the development of the Greek intellect in great part to "the sleepless critical spirit which shrank from no test of audacity," and this spirit he says was due to three causes. The metaphysical and dialectical discussions practised by the Eleatic philosophers and the semi-historical method which was applied to the myths by Hecatœus and Herodotus. The third cause is to be traced to the schools of the physicans. "One man practised in medicine verily outweigheth many other men," "this compliment," he says, "greets the medical profession at the rise of Greek literature. Posterity would not recall it."

He tells us of the fascinating picture of the earliest practice of medicine in India as depicted in the extent "Song of a Physician," who makes his jovial way through the land carrying his figwood chest of drugs, bespeaking for his patients recovery

*Presidential address before the Orange Mountain Medical Society, January 12, 1906.

and for himself a rich reward because he lacks "cob, cow, and coat." He is a slayer of demons, and diseases fly before his drugs as before the bailiff's grasp.

Gomperz alludes to the Indian art of medicine as portrayed principally in the Artharva-Veda (folk lore) and remarks that some of the rules of practice there laid down still obtain. As for instance, the use of the plant bright eye in ocular diseases, because a black speck present in its flower suggested the pupil of the eye, and the use of the blood stone or hematite to stop hemorrhage. The Egyptians maintained that the blood of black animals would prevent gray hair, and in modern Syria the ancient Indian doctrine is still held that jaundice may be expelled into yellow birds.

Even in those early days the art of surgery maintained its present excellent reputation of eschewing all forms of superstition and philosophical conjecture and achieving practical results by direct methods. He says "we are positively astonished at its (surgery's) high degree of cultivation amongst the nations of antiquity, and even in prehistoric times, as well as among the savages of today. They did not even shrink from operations of so bold a character as trepanning or the cesarean section." It has, of course, been generally believed that the latter operation was originated at the birth of the great Cæsar, who, we are informed, was "ripped untimely from his mother's womb." The operation having received its name from him, was naturally supposed to have been first practised in his case. A very obvious error.

The profession of medicine was fully recognized in Greece at a very remote period, and was in many cases liberally rewarded. The annual salary of Democedes of Croton from the city of Athens, the commonwealth of Aegina, and the tyrant of Samos, was 8,200, 10,000, and 16,000 drachmæ, or francs, a princely income when we consider the much greater purchasing power of money in those days. Democedes was afterward captured by Darius, King of Persia, where we presently find him seated at the royal table and acting as confidential adviser to the king; so "popular" had he become with the monarch that the Egyptian body physicians who had hitherto enjoyed the royal favor were utterly discredited and were even in danger of their lives. So about the middle of the fifth century before Christ Anasitus, a Cypriot physician and his brothers who had been active during the siege of Edalion by the Persians, enjoyed the highest honors and lived in princely style.

There were the swindlers and charlatans posing as doctors in their day as well as ours, and as Boas tells us patent medicines were sold in Greece in remote antiquity much as they are now in America, whether the formulæ of the contents were printed on the label of each bottle or package we are not informed.

Gomperz says, in reference to the quacks, that "the conscience of the profession, composed for the major part of honorable and capable men, suppressed if it did not expel those parasites on a noble tree."

The Hippocratic oath, a document of great antiquity, is a monument of the highest rank in the history of civilization, and the fact that succeeding classes of graduates in medicine have taken this oath, practically unmodified for over twenty centuries, before taking their places in the world as physicians, is a tribute to the sagacity, the sense of professional honor and responsibility, and the clear thinking of the Greeks, which needs no commentary from us. Prof. Gomperz remarks in regard to this oath "that in the complete absence of state control it formed the one public set of regulations for the practice of the art of medicine." Its spirit is exemplified in many of the medical writings of the day in which "the same pungent satire is directed at the arrogance of ignorance as at the humbug of quackery." "Physicians who were such in name, but not in fact," are compared with the "mute persons" or supernumeraries of the stage. The courage of wisdom is contrasted with the foolhardiness of ignorance. Touting for fees is deprecated, and a consultation in all doubtful cases urgently enjoined. The following quotation from these writings shows admirably the spirit of Greek, as well as of all true medicine: "Where there is love of humanity there will be love of the profession." It was called an act of deceit to dazzle the patient's eye by brilliant but unnecessary diplays of skill. Physicians were discouraged from holding public lectures in order to increase their reputations, and lectures containing quotations from the poets were especially condemned. Those who pretended to infallibility in detecting the slightest departure from their prescriptions were laughed at, and finally precise rules of personal conduct were laid down for the doctor. He was, as in these antiseptic days, commanded to observe the most scrupulous cleanliness, and was advised to affect an elegance without any signs of luxury, even down to the detail that he might use perfumes, but not in an immoderate degree.

Hippocrates was born in 460 B. C., on the island of Cos, and is justly entitled to the appellation "the Great" conferred upon him by Aristotle. A large collection of writings have been ascribed to his pen, evidently the work of many physicians whose identity remains unestablished. Gomperz, however, assures us that with a few inconsiderable exceptions, all the parts of the so-called "Corpus Hippocraticum" were written before the close of the fifth century B. C. It was, says Gomperz, "An age of the most rapid intellectual development, and of the most facile circulation of ideas," and of a great "reciprocal influence of medical and philosophical thought." "The elimination of the superstitious element from therapeutics went hand-in-hand with the release of the nations of antiquity from this general burden of primitive superstition."

Our author points out that the benefits undoubtedly derived from treatment in the priestly health resorts of those times were in part, at least, due to the salubrity of their situations as well as to the rational methods of treatment employed. He instances Epidaurus, the most famous of these resorts, which was situated in a hilly country in the heart of beautiful pine woods at no great distance from the sea. It was sheltered on the north by a range of mountains, and, with its precious springs of water, fulfilled all the requirements of a modern sanatorial establishment. It possessed a racecourse and a theatre, the stately ruins of which still remain. Naturally, superstition and priestly interference then as now obscured the true therapeutic value of these resorts, and in the detailed accounts of the cures obtained there the dietetic and therapeutic factors were omitted either from oversight or design.

However, the physicians of Greece shared with her poets and sculptors the same keen insight and the faithful reproduction of the object studied. In other words, Greek medicine was preeminent and a pattern to all succeeding ages, because Nature was carefully and truthfully studied and the results published, stripped of the fanciful and glittering flights of the imagination which obscured and mis-

interpreted the most common phenomena. It is not claimed that error did not creep in and that the philosophical spirit of the age did not allege many untenable and unscientific explanations for physiological and pathological phenomena.

The doctrine of the four humors of the human body, the blood, the phlegm, the black and yellow bile, corresponding in number to the four alleged elements, fire, air, earth, and water, seems to have been universally accepted in Hippocrates's time, and the disorders, changes, and altered proportions of these humors were for centuries asserted to be the causes of health and disease in man. Other beliefs equally untenable were taught and many absurd rules of practice followed, but as Professor Gomperz stoutly maintains, and as all students of this brilliant period and this remarkable people seem to agree, the progress made by the Greeks toward the establishment of a rational and scientific system of medical study and practice was, considering their limitations and the crude state of general knowledge, simply marvelous; and as we have hinted above, has placed all succeeding ages of medical men and the world at large under an obligation of the greatest magnitude. The reason for this dazzling result is that the Greeks studied nature; and, shaking themselves free from a load of superstition and ignorance almost inconceivably great, by turning their alert and polished intellects to the study of nature and her methods, achieved a success which was indeed phenomenal.

No real advance has ever been made in medicine by any other means, and no advance is possible by any other. The inductive method of reasoning must necessarily obtain in medical study, and to a certain extent is justifiable, but only by actual experiment and demonstration can real advance take place. Theories come and theories go. Divine revelations, exclusive systems, miraculous cures, all play and have played their little parts in medical history, but the good old Greek system of studying mankind as he is and interpreting the phenomena of health and disease as they appear to a truthful and unbiased mind is the only method by which medical or any other knowledge can be advanced. Fortunately to-day there are indubitable signs that medicine will in future be studied as the Greeks studied it. That the whole question of life, development, growth, and decay will be submitted to an exhaustive and scientific inquiry which must result in the greatest benefit to the race.

This method of considering the normal physiological existence from birth to death is returning after over twenty centuries spent in a more or less desultory study of symptoms and searching for remedies. No comprehensive view of the body and its functions seems even now possible to many students. False and foolish notions and improper methods of living and of education and development are still rife amongst the learned and the simple, the laity and the profession, but, thank God! a brighter day is dawning and we are getting back to the good old common-sense methods pursued by the father of medicine and his disciples four hundred years before Christ.

"We note in passing that the treatise of Hippocrates, 380 B. C. (on Masturbation), which ascribed the chief causal rôle to the spinal cord and gave it a fatalistic tone, was not excelled in acumen by any work upon the subject until the epoch-making treatise of Tissot in 1760." (Stanley Hall, Adolescence, Vol. I., p. 432.)

The fundamental rule not only of health but of education in those days was the synchronous development of mind and body. If physical education is so disastrous as some would have us believe, why it that the highest development of the intellect was coexistent with the highest physical development? Why is it that the Greek mind was not encased in a feeble and ill-developed body, if, as we are told by many *soi disant* authorities on such matters, the highest developed body is antagonistic to the best mental development? Why did those astute old Greeks not discourage instead of encourage bodily excellence and physical prowess? We never read that they advocated effeminacy or deplored the love of youth for out-door sports. On the contrary, among the brightest and best of these great men the crown of the successful athlete at the Olympian games seems to have been held in the highest honor and to have been as greatly esteemed as the prizes given for success in poetry or sculpture.

Whatever else may be said about these worthies it cannot be alleged that they were effeminate or one-sided. They were not dyspeptics or faddists. Nor did they evince that predominant trait among many writers of the present day to make the facts fit their theories. On the contrary, they studied Nature's ways and mankind as they really were. They appreciated the need of bodily exercise and delighted in physical beauty. They developed the muscles and the endurance in a way that has perhaps never been equaled, unless by the famous Roman legions, that conquered the world. And what was the result of the Grecian method of education? The greatest intellects the world has ever seen and the most magnificent human beings that ever existed—while modern therapeutists spend their time endeavoring to find remedies for the diseases due to gluttony and sloth, the Greeks insisted that man should use all his faculties in an appropriate and fitting manner if he wished to preserve them. While we, eaten up by luxury and self-indulgence, endeavor to find ways in which a man may circumvent Nature and transgress her laws with impunity, to the direct and logical mind of the Greek such a procedure was unthinkable. While we feed our patients with pepsins and predigested foods, the Greeks insisted upon simplicity in diet. While we distort the human frame divine by such absurdities as corsets and high-heeled shoes, the Greek studied Nature and did not endeavor, like the Chinaman and the American, to improve upon her. The beautiful human foot was admired by the Greek and preserved in its beauty and symmetry. What do we do to it? We have even gone so far as to pretend to admire obesity because so many of our slothful and gluttonous people are absurdly fat. To the simple, direct, common sense of the Greek such an incongruity was impossible.

However, let us return to our historian. He discusses at some length various of the books which constitute the "Corpus Hippocraticum." The author of a work in four volumes entitled "On Diet" says in the conclusion of his preface, "I contend that he who will write correctly on the subject of human diet must first of all know and understand the nature of man. Among his other demands this author insists that a knowledge must be had of the constitution of all food stuffs and drinks, and a comprehension of the far-reaching contrast between work and nutrition. "For the performances of work," he says, "are directed to the consumption of what exists, and food and drink are intended to replenish the void thus created."

The fundamental condition of health is a correct proportion between work and nutrition in view of the constitution of the individual and of the dif-

erences of age, season, climate, and so forth. Except for the one factor of the individual constitution, good health, in the opinion of this author, could be preserved from all disturbances. He then dilates upon a fanciful description of the two underlying elements of animal life which he ascribes to fire and water. His correct deduction from this erroneous theory shows the superiority of his observation over his theoretical reasoning. Similar observations upon the evils of overeating have been made by Euryphon, the head of the Cnidian school, an older contemporary of Hippocrates, who conjectured that the causes of illness lay in a surplus of food. And Herodicus, another Cnidian, who said that men fall ill when they indulge in food on insufficient exercise.

The author of "On Diet" speaks of the belly as the universal "storeroom which provides for all and receives from all." He also speaks of the steady ceaseless "transformation" of matter and reduces all "death and decay" to "combinations and separations," and relates at least one original experiment, namely, that of artificial vomiting in order to test the varying digestibility of foods simultaneously consumed. Thus he antedated and set the fashion for the prevalent test breakfast. In a work "On Dreams" certain of these were traced to overfeeding, and the treatment recommended was an aperient.

Gomperz then discusses a treatise "On the Muscles" and describes the author as a practitioner "who has seen much and observed keenly as long at least as his faculties of sight and observation were not obstructed by preconceived opinions." He was the first to recognize that the so-called spinal marrow is entirely distinct from the common marrow of the bones, that it possesses membranes, and is related with the brain. He also had seen cases of suicides who had attempted to cut their throats and had lost the power of speech by penetrating the trachea and allowing the escape of air. Speech had been restored by closing the wound; from this he rightly drew the conclusion that the power of speech depends upon the proper passage of the air through the trachea and larynx. He also performed various experiments upon the coagulation of the blood, and studied the composition of various tissues of the body by boiling them and noting the different effects of this process upon them.

He then, after the manner of the day, became involved in a learned philosophical dissertation upon the wonderful number 7, and declared that no eight-months child can live. A superstition still extant. Among other things, he claims that abstention from food and drink beyond seven days must be fatal, either within that period or, as he naïvely added, at some subsequent time. Even those who, after the expiration of seven days, desisted from this method of suicide, suicide indeed being by no means rare in antiquity, were, according to the author of "On the Muscles," irretrievably lost, for their body had become incapable of assimilating nourishment. Gomperz adds: the vigor of our author's thought did not save him from the spell of number, and in other directions, too, he succumbed to the wiles of the imagination.

In speaking of the real progress which medicine made in spite of the all-pervading nature-philosophy, the reverence for numbers, etc., Gomperz says: "The apprentice years of the mere collection of facts were followed by the Wanderjahre of vague, restless speculation. These had now lasted long enough, and it was time for the Meisterjahre of quiet, methodical research to succeed, if science was to acquire steady and sedentary habits, instead of losing itself in a maze of phantasies, revolving in idle circles. It is to the undying glory of the medical school of Cos that it introduced this innovation into the domain of its art, and thus exercised the most beneficial influence on the whole intellectual life of mankind. "Fiction to the right! Reality to the left!" was the battle-cry of this school in the war they were the first to wage against the excesses and defects of the nature philosophy.

It is certainly amusing to find in this collection of writings a book "On Old Medicine," whose author condemns the "new-fangled" art of healing. Among other things this champion of the old régime gives is the following: "But the healing art possesses all things from of old, a principle, and a beaten track along which in the course of ages many splendid discoveries have been made and along which the science will be perfected if men of adequate talent, equipped with a knowledge of the discoveries made hitherto, take these as their starting point, and set out thence on further inquiries. He who rejects and despises all this, however, and undertakes his investigations on another road and in other forms, and claims to have discovered something, he is deceived and deceives himself, for it is impossible." Truly a conservative man and a believer in the established order.

His treatise, like so many of the others, deals mainly with dietetics. He refers to the improvement and elaboration of the cuisine, speaking of the transition from the coarse nourishment which men shared with the brute to refined cookery and varied diet then in use, and characterizing the latter as "a great invention, elaborated and perfected in the course of centuries with no mean display of intelligence and imagination." He adds, "one must aim at a standard, but a standard weight or number which shall serve thee as a sure guide thou shalt not find, seeing that there is no other than the sensibility of the body."

He was indeed a wise man and a correct reasoner, if one admits his premises. In another place he says, "But I believe that all that sophists or physicians have said or written about nature belongs less to the art of medicine than to that of painting." . . . "There is a long road still to be traveled before that degree of erudition is reached which shall know what man is, by what cause he was created, and all else to the least detail." Prof. Gomperz examines the writing of this author in considerable detail and comments with learning and skill upon the entire trend of medical and philosophical thought of the time. He says that the false deductive method was buried in the ruins of the philosophical theory of medicine and the correct inductive method was borne in on the triumph of Hippocrates.

The undying glory of the School of Cos does not rest in the selection and use of methods of research better in themselves or nearer to ideal perfection. Their chief title to esteem is rather the insight they displayed in perceiving that the premises for the application of the deductive method were not yet extant, that they had not even come in view, and that fantastic conceptions were taking the place of requisite and valid inductions." The pioneer virtues which distinguished the Coic masters from their opponents were a self-abnegation and a timely renunciation of ambitions, fascinating enough and even exalted in themselves, but at that era and long afterward out of reach, and these virtues entitle them to our ungrudging admiration and imitation at this day.

We recognize their superior merit in having de-

veloped with tireless powers of observation and extraordinary faculties of clear sight and strong sense, those branches of the art of healing which were capable of extension without digging their foundations more deeply. Above all, we may specify their contributions to symptomatology which by their endless supply of nice distinctions and acute observations are a source of pleasure and instruction to modern students of that branch of learning. Unfortunately, however, they could not wholly renounce the construction of comprehensive theories. To the absurd doctrine of the four cardinal humors they were irrevocably committed. However, in the main their teaching and doctrines were founded in reason and common sense; at an early date they took as strong ground in opposition to the supernatural theology as they had against the fantastic excesses of nature-philosophy on the extravagances of the metaphysical theories. In the book "On Water, Air, and Sites," one of the most remarkable of the Hippocratic collection, an energetic protest is uttered against the assumption that the so-called "feminine disease" of the Scythians was due to a divine visitation, and in almost the same words the same notion is combated in regard to epilepsy, in the book "On the Sacred Disease." By this name epilepsy was designated on account of its alleged divine origin. In both cases the denial of divine or supernatural intervention was accompanied by the assertion of the compatibility of a uniform obedience to law in all natural phenomena, with a belief in the divinity as the source of all of these phenomena. "Everything is divine and everything is human," says the author of "On the Sacred Disease," and he added that it is unreasonable to call one disease more divine than another. This writer displays a strong antipathy to quackery, and alludes in scathing terms to the "windbags and street-corner prophets" who undertook to cure diseases by the practise of purifications and incantations, and who sought to conceal their own ignorance and impotence "under the mantle of the divine," and who might be shown in the clear light of day to disbelieve the truth of their own teaching, much, indeed, like the pretenders and charlatans of our own day. This treatise also claims our consideration for its reaffirmation of the significance of the brain in the physical and especially in the psychical life. In fact, its author had apparently made the important discovery that epilepsy springs from disease of the brain.

Gomperz concludes this masterly chapter of his work as follows: "Nothing is lacking to prove the contention from which we set out, that the study of medicine was the source of the third great wave of criticism which poured its fertilizing stream over the fields of Greek learning. . . ." We are reluctant to part from the precious collection of the Hippocratic writings which are still so little known and appreciated, without offering a few more proofs of the sound scientific spirit which penetrates a considerable portion of them. One of the most generous marks of that spirit is an appreciation of the great thoughts originating from an opposite or hostile school. The author of the work on "Diet in Acute Illnesses" displayed a genuine spirit of research in his endeavor to strengthen the doctrine which he was combating when he wrote in one place, "My opponents' view will be assisted by the following consideration. . . ." No less sturdy and incorruptible was the instinct for the truth evinced by the author of the work "On the Joints," which Littré characterized as "the great surgical monument of antiquity and a model for all future ages." The writer, a physician of noble mind and lofty thought, did not shrink from recording his own failures for the information of his fellow-investigators. He says, "I have written this down deliberately, for it is valuable to learn of unsuccessful experiments and to know the causes of their non-success." In another place, "It may be urged," he wrote, "that such questions lie outside the precincts of medicine, for what profit is there in a further study of cases that have already become incurable? Such arguments I am sure are very wide of the mark. In curable cases all pains must be used to prevent their becoming incurable; but incurable cases must be recognized as such, in order to save the sick man from useless mal-treatment."

Nor was he otherwise disposed to spare his own exertions. He had the joy of work which is a true mark of genius. In this way he extended anatomical research from the human to the animal creation; he compared the structure of the human skeleton with that of other vertebrate animals, and two passages in his work speak so eloquently of the grandeur of this attempt that we do not hesitate to entitle him an early, if not the earliest, pioneer of comparative anatomy. But we conclude by citing an important generalization due to the same powerful intellect, the brilliancy of which is testified by the wide range that is described, by the evidence constantly increasing of the truth of its contents, and by the deep significance of its consequences. We refer to the maxim touching the necessity of function for the preservation of health in an organ.

"All parts of the body," he wrote, "which are designed for a definite use are kept in health and in the enjoyment of fair growth and of long youth, by the fulfillment of that use and by their appropriate exercise in the employment to which they are accustomed. But when they are disused they grow ill and stunted, and become prematurely old."

Verily "the new things" in medicine are the things which have been forgotten. The wisdom, erudition, and industry of these pioneers of our art excite our wonder and our admiration, and scarcely less does the clear and logical exposition of these remarkable men and the influence which they have exerted on the intellectual development of mankind call forth our gratitude to Professor Gomperz, from whose great work I have so freely borrowed.

A PLEA FOR MORE CONSERVATIVE EXAMINATION IN SUSPECTED CASES OF PULMONARY TUBERCULOSIS.

By CLAUDE C. KEELER, A.M., M.D.,

DENVER, COLORADO.

The time spent in examining cases of pulmonary tuberculosis is indeed very limited, more so among the general practitioners than among the specialists, and, as a result of my observations, gained while examining a number of such cases, I have come to the conclusion that the time spent in former examinations of such patients was, on an average, from ten to thirty minutes. Of course, as we well understand, in cases that are well advanced into the second stage of the disease, it requires but little time to pronounce a diagnosis. It is not our intention to discuss the latter stages but merely to take up the earlier stages of this dreadful malady.

Before proceeding farther on this subject, we would call your attention to a few cases which recently came under our consideration: Mr. H., from southern Wisconsin, a lawyer by profession, thirty-six years of age, had been under treatment by his

family physician for seven months previous to his coming West. His first symptoms, upon consulting his physician, were: Occasional, slight, hacking cough, no expectoration; but, as usual, the cough was not given a thought; he had been having considerable distress in his stomach about an hour after eating; at times anorexia; or, if the patient had a good appetite, it was gratified at the expense of great suffering. It was for this gastric disturbance that he consulted his physician, who informed him that he had only a slight attack of indigestion, and who prescribed without making any further examination of him. The patient improved for a few weeks, but was not at any time free from his symptoms, and he informed me that at no time during his entire treatment were his pulse and temperature taken. It was in the late fall that he had occasion to visit Denver, and it was while in this city that he came under our observation. It had been about seven months since the appearance of his first symptoms, and he had lost about fifteen pounds. There was slight dyspnea, perhaps due to the altitude, but more likely due to the anemia that existed. We observed the following symptoms: Pulse rate from 80 to 115, and at times very feeble; temperature as follows: 7 A.M., 97°; 9 A.M., 97 2-5°; 12 M., 99°; 2 P.M., 100°; 4 P.M., 100 1-2°; 6 P.M., 99 2-5°; 9 P.M., normal; and at 10:30 P.M. it had dropped to 97 1-5°. He told me that he had lost considerable color during the past year, but had never suspected tuberculosis. Upon physical examination, the conformation of the chest was the first thing to arouse suspicion, the thorax being long and narrow, with comparatively wide intercostal spaces. The left clavicle had a tendency to stand out more distinctly than the right, with defective expansion at left apex. While the patient at no time complained of pain in the lungs, yet he told me that during the past sixty days, upon arising in the morning he would have a short spell of coughing, and perhaps one or two during the day, the expectoration having a glairy, sagolike appearance. It required ten different microscopical examinations of the sputum before we were able to detect the tubercle bacilli. Diagnosis: incipient tuberculosis. We immediately put the patient under treatment, and at this time cough has entirely ceased and he has gained in weight. Under proper care and treatment we see no reason why this case cannot make a complete recovery.

Mrs. C., from a small town in eastern Kansas, aged thirty-two, the mother of two children, was sent to Colorado by her physician, for quick consumption. She had recently recovered from an attack of pneumonia (I think lobular), but had not been in good health since her recovery; coughed a great deal, with free expectoration, the sputum in character being of a creamy pus, at times very offensive; there were slight chills and fever at different times during the day, anorexia, and she had lost considerable flesh. She told me her physician had never made a microscopical examination of her sputum. We examined the sputum at several different times, but failed to find the tubercle bacilli. Physical examination revealed a perfectly normal chest, with the exception of signs of cavity, which at times seemed to be empty, and in the course of several hours would fill up. We made a diagnosis of abscess of the lung and advised an immediate operation, which was refused. We put the patient on the tincture of chloride of iron and sulphate of quinine, together with antiseptic inhalations of carbolic acid, creosote, etc., and instructed her to keep out of doors as much as possible, with the result that an uninterrupted recovery followed.

Mr. A., druggist, single, aged forty-two, consulted me last April, giving me a history of having recovered from a siege of grip about six months previous; he had had a continual hacking cough since his apparent recovery, and was very susceptible to colds, which would aggravate his cough; he had slight attacks of indigestion, which would usually respond to treatment, until the past ten weeks, during which time treatment seemed of no avail. His former physician's diagnosis was gastritis, accompanied by bronchial irritation (which is very often the sequel of grip), and that he would probably obtain but little relief from the latter until spring had well advanced. He had always enjoyed comparatively good health up to the time of this attack, but he informed me that he had been rooming with a young man who was affected with pulmonary tuberculosis, and who had been compelled to leave the city. It was only a short time after his roommate's departure that he was taken down with this attack of grip, but still occupied the same room, and was confined to his bed for several weeks. At the time we examined him, he had practically a normal temperature morning and evening, reaching its maximum of 100 2-5° about 2:30 P.M. When he was free from his gastric symptoms his appetite was good; he slept well at night, with a coughing spell on arising; pulse, 90 to 120. There was nothing in the shape of his thorax to indicate that he was the victim of tuberculosis. We had this patient under careful observation for eight days, and finally made a diagnosis of incipient tuberculosis.

We could bring to your attention a number of other cases, but think the three above referred to are sufficient to give you a proper idea of the limited time spent in the examination of such cases. While it is true that the diagnosis of incipient tuberculosis is extremely difficult, yet at the same time the physician who is consulted by a patient who gives him the following symptoms: Attacks of acute indigestion, chronic bronchitis—with or without expectoration—anorexia, dyspnea, slight or no rise in temperature, tachycardia, little or no loss of flesh, etc., should make a very careful examination of the case. Should the patient give him only a few of the above symptoms, it should at least be sufficient to arouse suspicions as to the probable diagnosis. I do not mean to convey the idea that a patient with these symptoms is always afflicted with tuberculosis, but it is usually in patients in this condition that the earliest signs and symptoms are overlooked by the attending physician.

Several examinations should be made on different days and at different hours of the day, in order to get the range of temperature and ascertain the correct pulse rate morning, noon, and night. A vast majority of the profession, upon having their suspicions aroused in regard to a possible case of pulmonary tuberculosis, will perhaps make a hurried examination, of a few moments' duration, without as much as baring the chest. With such an examination it is absolutely impossible to ascertain the conformation of the chest; neither will palpation, percussion, or auscultation be at all satisfactory; the examiner, being unable to find dullness on percussion, or râles by auscultation, informs his patient that his lungs are in a perfectly normal condition, when in reality he is the victim of incipient tuberculosis. A number of cases of advanced tuberculosis are due to the negligence of physicians, who, upon their first examination of the patient, fail to recognize the disease, and it is only in the course of a few months that your patient again consults you, but now with well-marked signs of tubercular infection. Indeed, the patient's chance for recovery at this time is much less than it would have been had the disease

been properly diagnosed a few months previous, and the patient been given proper instructions in regard to his condition, together with a rational line of treatment.

While it is very true that there are countless numbers of these patients who do not consult their physicians until the disease is well advanced into the second stage, yet, on the other hand, there are thousands who do consult their physicians upon the earliest manifestations of ill health, and it is in this class of patients that physicians make their greatest errors in diagnosis, as they look upon the cases lightly and do not devote sufficient time to the physical examination to warrant them in making a correct diagnosis. I do not mean to make the assertion that the diagnosis should be made from the physical signs alone, but that they do indicate the condition of the organs examined, and from the consideration of these physical signs, together with the constitutional symptoms and history of the patient, the diagnosis is made.

To properly understand the physical signs that are caused by abnormal conditions of the thoracic viscera, it is very essential that the physician should be able to recognize and thoroughly understand the normal physical signs. We will not monopolize the space or time in discussing the normal chest, but will take up a few of the abnormal conditions usually present in the earlier stages of pulmonary tuberculosis.

In making the physical examination, the patient should be stripped to the waist, and may be examined in either the sitting, standing, or recumbent position, but it is very important that the position be a comfortable one. In the majority of cases you will find a local retraction of the chest wall, which is generally due to contraction or collapse of the lungs, and is usually seen at the apices, or, if the retraction be at the base, it is generally the result of empyema or adhesions. The shape of the chest is often suggestive, although pulmonary tuberculosis may be met with in any type or build of chest; but in the great majority of cases the thorax will be long and narrow, the costal angles very narrow, and the ribs more vertical in direction, with very wide intercostal spaces. At times the lower sternum forms a deep concavity, the so-called funnel breast (Trichter-Brust). One of the early and most important signs is defective expansion at one apex. A great amount of good has been accomplished by the examination of the chest with the *x*-ray, as the normal lung tissue is easily traversed by the ray, and should there be any change in density in the lung tissue it is indicated in the fluoroscope by darker or lighter areas. The diaphragm is easily seen during respiration, and, normally, should descend from one and one-half to two and one-half inches in respiration; and frequently limitation in the excursion of the diaphragm is one of the earliest signs of pulmonary tuberculosis.

Hippocrates described the physical signs of tuberculosis in the following terms: "The forms of body peculiar to subjects of phthisical complaints are the smooth, the whitish, that resembling the lentil; the blue-eyed, the leucophlegmatic, the reddish, and that with the scapulæ having the appearance of wings."

The flat chest with depressed sternum is very commonly seen in tuberculous patients, but, as we said before, there are many individuals with perfectly normal chests who fall victims to the disease. The old idea of hereditary consumption must be relegated to the shelf, and in its place comes the more advanced theory that it is purely an acquired disease. The scrofulous or tuberculous diathesis is now regarded only as an indication of a type of conformation, in which the tissues are much less capable of resisting infection.

Mahomed and Galton, in making a study of the composite portraiture of pulmonary tuberculosis, have separated two types of face: One coarse-featured and broad, the other narrow and ovoid; but these types are by no means characteristic, as they may again take the same number of patients and find an altogether different type of face.

In making the examination of a suspected case of pulmonary tuberculosis, it is very essential that the physician should devote considerable time to palpation, percussion, and auscultation. Palpation will enable the observer to denote the irregularities in form, local expansion, local points of tenderness, pain, etc. It must be remembered that the intensity of the vocal fremitus varies greatly in different individuals, and is much more marked in men than in women, and that it is diminished by anything which interferes with the transmission of vibrations to the palpating hand; as in bronchi partially filled with mucus, very thick chest-walls and pleural effusion. The fremitus is greatly increased by consolidation of the lungs, as it makes a much better conducting medium, and it is important in making a comparison of the apices to bear in mind that the fremitus normally is much stronger over the right than the left. By placing the fingers in the infraclavicular space, and the thumbs in the supraclavicular space, and standing behind the patient, the observer can get a fair idea as to the relative mobility of the two sides, and should there be deficient expansion at an apex, even before dullness is at all marked, it is an indication of disease. Very accurate information can be obtained by percussion if it is properly practised; but the technique of percussion is by no means an easy art, and a great many more mistakes are made by this method of examination than by any other. The mediate method of percussion is much more satisfactory than the immediate, as it better enables one to distinguish between the different graduations of pitch. The lungs should be percussed during both inspiration and expiration, and should you be able to detect dullness it is an indication that the lung tissue is encroached upon by solid organs; or, in cases of pleurisy, with effusion, and enlargement of the heart, spleen, or liver will cause dullness on percussion.

In the very earliest stages of tuberculosis dullness is detected at the apices of the lungs, due to the presence of tuberculous deposit. The flat percussion note is always an indication of disease, with the exception of when the percussion is made over solid organs; but the flat percussion note is seldom recognized in the earlier stages of tuberculosis.

For the diagnosis of incipient tuberculosis, auscultation affords by far the most satisfactory method at the disposal of the physician, but it is important that the observer should be familiar with the normal pulmonary murmur, and his sense of hearing be at the best. Râles are never heard in the normal chest, and the character of the râle always depends upon the point at which the sound is produced. Crepitant, subcrepitant, and mucous or bronchial râles, are all noted in pulmonary tuberculosis, but the crepitant râles are most frequently heard in incipient tuberculosis. They are the finest of all râles, and have a dry, crackling sound, which is heard only at the end of inspiration. It is often a difficult matter to accurately determine the character of the râle, and if the physician is not accustomed to such examination, and his hearing is not well trained, it is quite likely that the râles will not be heard. Subcrepitant râles are much easier to distinguish than

the crepitant, as they are heard both during inspiration and expiration. They are in character fine and moist, and usually disappear when the patient coughs. The mucous or bronchial râles are due to the same cause as the subcrepitant, with the exception of the point of production being in the large bronchi, which makes the sounds much more audible.

I will give, as my conclusion, that if the profession will spend sufficient time in the examination of suspected cases of incipient tuberculosis to warrant them in making a correct diagnosis, at the end of twenty-five years the mortality of this dread disease will be reduced to a very low percentage.

Finally, I want to add that should the physician, after a thorough examination of a patient, entertain a doubt as to the diagnosis of the case, he should be seen by one who is familiar with the earliest manifestations of the disease, and by one who has become accustomed to the treatment for the relief of such conditions.

INTRALIGAMENTOUS DRAINAGE FOR NON-SUPPURATING PARAMETRITIS, WITH DESCRIPTION OF TECHNIQUE.

By LEON F. GARRIGUES, M.D.,

NEW YORK.

ATTENDING GYNECOLOGIST ST. MARKS HOSPITAL; SURGEON, WEST SIDE GERMAN DISPENSARY.

On May 26, 1900, I published an article in the *Medical News* on "A New Operation for Retroperitoneal Drainage of Pyosalpinx." Since then I have employed the method for a variety of purposes, have had no deaths, and, so far as I know, no recurrence of suppuration in any case operated on. In this paper I will speak of its use in parametritis, and will give some indications for operating in this condition, which differ somewhat from those in use. I will not weary you by going over in detail the signs and symptoms of parametritis, but will dwell only on such points as are but little known or new.

Parametritis is a cellulitis situated between the layers of the broad ligaments, the sacro-uterine ligaments, or, rarely, between the uterus and bladder. The variety which concerns us especially and which is by far the most common is that of the broad ligaments. If, after an abortion or confinement the patient is seized with a chill, rise of temperature, and a mass can be felt to one side of the uterus extending rather low down, and the induration joins that of the uterus on one side and the pelvic wall on the other, we have to do with a parametritis. This may resolve, become chronic, or suppurate. If there is an intense septic process the mass will enlarge, invade the other ligament, and not rarely the sacrouterine ligaments, and other pelvic cellular tissue. It also spreads to the neighboring peritoneum, tubes, ovaries, and bladder. It is this extension, with its great possibilities for permanent harm to the pelvic organs, that I design to avert.

In chronic parametritis there is a hard, somewhat tender mass between the layers of the ligaments which shows very little inclination to resolve; and even when it does, leaves the parts thickened, inelastic, and tender. The patient in the meantime is suffering from a low grade of sepsis, which greatly undermines her health. I have seen such cases confined to bed for months under treatment with only a partial recovery at the end. Sometimes there are small collections of pus in the center of these masses, which remain quite unsuspected by the gynecologist, because the fever is insignificant or absent, and the mass is of stony hardness.

Now, if we turn to our textbooks for advice we find that these cases should be treated by various douches and applications, unless pus develops, as evidenced by fluctuations, or at least softening of the mass with recurring chills and fever. These signs and symptoms may occur when the abscess has burrowed its way close to the surface; but it may also burrow into an intestine, or bladder, or rarely into the free peritoneal cavity. I claim that the diagnosis of a small collection of pus in the center of a hard mass, often the size of an apple, cannot be made unless (which is rare in the chronic cases) chills and fever lead one to suspect its presence.

The indications for operation (in the acute cases) which I advocate are: Temperature over 101°F, particularly if the pulse rate be high, chills occur, and the patient has a septic appearance. Cases in which on the first visit there is a small swelling, and on the following day a larger one, showing extension of the process. I do not mean that these symptoms indicate that pus has formed; quite the contrary; my aim is to open and drain the parametrium before the process has had time to spread to the neighboring organs, on the same principle that we incise a cellulitis of the arm that threatens to spread beyond our control, whether pus be present or not.

My method of operating is as follows: After curetting the uterus the cervix is drawn toward the healthy side, and a bullet forceps inserted in the vagina to the side and slightly posterior to the cervix, so as to put the vagina on the stretch. An incision is made through the vaginal wall close to the uterus about three-fourths of an inch in length. Through this incision the forefinger is inserted, and, keeping close to the uterus, is pushed well up between the layers of the ligament into the hard parametrium and then outward, so as to open up the mass freely for drainage. Should the Fallopian tube be much swollen it is opened by means of a blunt forceps, under the guidance of the index finger. A good-sized tube of large caliber is introduced either in the parametrium, or in the tube, as the case may be, and the operation is complete. If no pus is present a small quantity of bloody serous fluid escapes. I have never had to use an artery forceps, and have had no deaths following this operation.

Case I.—Miss S., on the third day after an abortion had been induced, developed chills and fever. When I saw her she had a temperature of 103° F., and a pulse of 110; vaginal examination elicited a hard, tender mass in the right broad ligament. I urged immediate operation, which was declined. On the next day the temperature was 104°, and the patient was delirious at times, and obviously in an intensely septic condition. The mass in the ligament had increased somewhat in size. I then obtained consent to operate, which I did according to the above-described method. On the next day (the fifth after the abortion) her temperature rose to 105°; on the sixth day pus began to come from the tube. On the ninth day the temperature was practically normal, with a free discharge of pus from the tube. After this the suppuration decreased rapidly, and on the sixteenth day only a few drops of pus came away; the hard mass in the parametrium had disappeared, leaving only a little thickening in its place. The tube was then removed, and the patient made a rapid and complete recovery. I examined her some time later and the only abnormality that could be felt was a small scar in the vagina. By the way, it is a constant rule that the

temperature rises the first day after operation, and then begins to subside, but the temperature does not become normal until free suppuration has been established.

I will give the details of only one acute and one chronic case, as the cases all run about the same course, excepting that some heal more rapidly than others. When the temperature drops to normal I allow the patient to get up, as the cavities drain better than in the recumbent posture. When we are called to treat a case of chronic parametritis the conditions are somewhat different, and we can take more time in deciding on an operation. I have treated such cases for months by pelvic massage, ichthyol and glycerin tampons, hot douches, etc., and obtained fairly good results, but the method is at best tedious, and uncertain in its results. It is now my rule to advise operation in all cases which have lasted one month without much shrinkage in the amount of the exudate. If the patient shows signs of septic absorption I urge operation at once.

Case II.—Mrs. M. had since her confinement suffered with a parametritis of both sides, giving rise to a temperature of 100° F., pelvic pains, weakness, lassitude, anorexia, etc. She had lost much in weight and was a semi-invalid when I was called in, two months after her confinement.

Vaginal examination showed a double parametritis, very hard, and moderately sensitive to pressure. I operated as previously described, leaving a tube in each broad ligament. The second day the temperature rose to 101.6° and for several days was slightly above normal; then suppuration set in and the temperature dropped to normal. She made an uneventful recovery. In some of my earlier cases I made the mistake of not opening the mass freely enough, hence only part of the inflamed parametrium was drained, with the result of a tedious recovery; and in one case an extension of the inflammation to the peritoneum, which gave rise to a pelvic abscess which had to be opened through the abdominal wall. The patient is now in excellent health.

In opening any inflammatory pelvic collection I would urge against the use of sharp perforators, scissors, etc., as they are liable to enter the free peritoneal cavity, and I have seen dangerous bleeding follow their use. The finger is decidedly the most accurate and harmless instrument that can be used, as it does not tear veins or arteries.

In conclusion, I would state that the operation is not dangerous, usually not very difficult, and the results are certain and satisfactory.

210 West Fourth Street.

FOOTBALL AND MORAL HEALTH.

By WILLIAM LEE HOWARD, M.D.,

BALTIMORE, MD.

As a physician who daily sees mental and moral instabilities—the result of indifferent fathers, coddling mothers, and complacent teachers I say to college authorities: Place no barriers, subjectively or objectively, against football. I know of many miserable beings who, had they been allowed, or forced, at school and college to play football, would have been men to-day able to give the world lifts in science and literature—individuals who are wrecks because they were not allowed to run the risk of a bruised limb, or to learn Nature's laws and of physiological growth.*

I have deep feeling in this matter, and say without reservation that a boy with a broken leg from football has a far brighter outlook for future success in life than the coddled son of a mother who will not look physiological facts in the face and learn that physical expression of activity is the only healthy channel for the expenditure of youthful energy, and if prevented this energy will be wasted along the line of immorality which will leave scars and wounds that last throughout a miserable existence.

I also frequently see that anti-social being—the effeminate male. Football in boyhood might have so developed certain brain cells as to have made him a social being.

To the pedantic college presidents I say that football is one of the greatest factors we have ever had in school and college for producing moral men. There is a tremendous force for moral health in football and all rough games.

The present conditions under which we live are full of hypocrisy and inverted modesty. The sublimest of Nature's laws have been ignored by uninformed teachers and hidden in a cowardly manner by those physicians who bend under the yoke of social convention or rest in the lap of silence.

Training for football teaches hygiene and instructs in the laws of Nature. Take a boy away from such influences and let him be under those who would substitute mild games and effeminate ideas, and under these conditions the youth cannot be himself. Dissimulation is the mother of lies, and as the teacher is, so will be the youth. Any college professor who has kept *en rapport* with the trend of student affairs realizes that the *morale* of the undergraduates is better than that of twenty years ago. This is not due to religious training or didactic moral instruction—in fact, there is little of these latter puritanical ideas left—but is due to football and all that its good influence implies. "The tone of morals and the character of the habits of the student at the present time is far above—in real excellence—the quality of the time of fifty years ago. There is less drinking and less of all forms of abominations now than in my day, and I believe that a great deal is due, not to any increase of piety among the professors, but largely to practice of the ball games of the present time, especially football, that it enables the boys to throw off an amount of steam and force and excitability in a legitimate way, which in my day was expended in illegitimate and unmanly ways, and ways of a sad moral influence." —A college professor who graduated fifty years ago, quoted by George Meyland, Director of Gymnastics, Columbia University; New York *Times*, August 12, 1905.

Explosion of physical energy is the birthright of every healthy youth, and any attempt, advisory or otherwise, to suppress this bubbling activity is an injustice to the growing man. Let rules be made governing the management of games and eligibility of players, but allow nothing that will discourage the cultivation of the normal spirit of resistance. A spirit of non-resistance under provocation or in athletic contests is unmanly, craven, and belongs to the unsexed. A boy to be a man must have the physical fighting instinct. If his school and college days are properly directed this instinct will be diverted to football, wrestling, or boxing, and rightly but roughly directed. We want no pietetic odor around boys' games, nor any atmosphere of timidity; but strong, virile, rough, dangerous, if you will, contests that make against moral and physical degeneration.

I am speaking only of the true spirit of resistance. The *sacra animi tempestas* of anger is an entirely different form of explosion. The youth with a quarrelsome, bullying nature finds no place

**Advanced Scholarship and Morbid Mental Conditions*, William Lee Howard, M.D. Medical Record, July 1, 1905.

in college games; he is an anti-social being who is either harshly and successfully corrected or ostracised. Football contests have been the channel through which normal youthful energy has been properly directed and many a youth made into a self-governing man who otherwise would have been a physical and moral nonentity.

Many unfortunate, pitiable beings have said to me: "Oh, doctor, if I had been allowed to play, swim, or jump with the boys! My father never told me anything of life and my mother would not let me play football at school. She was afraid I would get injured." College presidents should see this reverse side of the question. Nothing is more inspiring than excessive youthful energy. This must find an outlet, and the man will be according to this vent. Attempt to suppress this activity and the youth turns to sourness and underhand methods. Ignore this adolescent volcano and you get a flabby manhood or an effeminate being upon which immorality fattens. Better broken bones, physically crippled for life, yes, better death, than psychic perversion and bodily corruption.

It is the penetrating indirect effect of football that is the beneficial factor among the mass of students. This good influence extends to the preparatory schools, and has here great power for moulding the character of the youths. Here is established a standard of honor in breaking training. In learning to subordinate self to school interest there is eliminated those selfish traits so many boys are apt to bring from home. Both at school and college there is cultivated a feeling of emulation for strength and health which means the absorption of hygienic knowledge and physiological facts which no amount of didactic teaching or textbook reading would impart. The rough games at the high schools eliminate to a certain extent those physically unfit for college. Too many undeveloped youths have in former years gone from the coeducational high schools to colleges where their careers were shortened through inability to withstand the physical pressure.*

The beneficial influence of football is exerted on the student masses throughout the country; enters the homes where the school boys read with avidity the latest college news, and sends the blood rushing through the veins of the tired father. Both at school and college it brings out ideas of students in writings and debates who otherwise would be noninterested and slothful. Studies in strategy become interesting, and conversation is free from silly gossip and salacious tales. It offers opportunities for discussion which often arouse the slow thinker and the indolent. It teaches respect for deeds, for self-sacrifice and consistency of purpose. It teaches all students diet, regimen, and the necessity of keeping the body clear of its poisons. These important details in developing the youth into a healthy, normal man cannot be enforced with any regularity by rules laid down by college authorities. Youths, like their aboreal ancestors, hate the monotony of method. The standard set by the football squad is followed without any knowledge of compulsion, and hence has its excellent effects. Even the most slothful will sporadically indulge in some form of rough exercise, which acts as a purgative in eliminating through the normal vent excessive physical energy.

Sons, fathers, sisters, all receive physical benefit from witnessing football games. But it is in the student spectators that the healthful influence is mostly seen. The psychic excitement before the game which has kept the student mass keyed up to explosive tension has opened the veins and arteries, kept the heart rhythm vaccillating and the nervous system active. The training, the condition of the men, the reason for certain details of life are all actively followed. The physical relief which comes from witnessing the game is well marked. The howling, yelling horde of adolescents, their dancing and singing, grotesque costumes and ridiculous rhymes and the apparently mad leaders, are not signs of reversion to our savage ancestors but an expression of normal physical energy. This howling and physical expression of enthusiasm produces an erethetic intoxication at an age when every artery, vein and muscle can respond to tension and flushing, enlarging the caliber of blood vessels and forcing the blood to irrigate newly growing fibers and cells. It is a grand feeding process, and the psychic activities respond to the normal stimulus. "The soul is expanded, the brain receives the oxygenated blood, and new ideas are germinated, and the youth is safely on the physical and mental road to strong manhood" (President Stanley Hall).

Eliminate any of the risks in the game, suppress any of the powerful animal instincts which the game must bring out, throw a mantle of pedantic authority over the rules, and you will bring about an atmosphere of timidity and effeminacy which will rob football of all its direct benefit to our youths and young men.

*"Sex Differentiation and Education," William Lee Howard, M.D., *New York Medical Journal*, February 20, 1904.

CHOREA AND SOME DISORDERS SIMULATING IT.*

By AUGUSTUS A. ESHNER, M.D.,

PHILADELPHIA, PA.

There are many reasons for believing chorea to be an acute, self-limited, infectious disease, with possible relations to acute rheumatism. A noteworthy parellelism in prevalence exists between the two diseases, and symptoms of the one not rarely precede or follow, or even coincide with those of the other. Both are frequently complicated by endocarditis, and it has been possible by inoculation of lower animals with microorganisms cultivated from the lesion to produce the symptoms of both diseases. The two disorders may be viewed as representing different localizations of the same infection.

The neurotic temperament is an important predisposing factor in the etiology of chorea, and heredity, direct or indirect, plays a significant part in this connection. The individual attack seems at times to be precipitated by emotional influences, such as fright, but the association may be merely coincidental.

Chorea is especially a disease of childhood and adolescence. It occurs more commonly in females than in males, in the proportion of 2 to 1. It affects all classes of society, although it is more common in the city than in the country. It is rare in negroes and Indians. The largest number of attacks occur in the spring of the year.

The characteristic and usually the most obtrusive symptom of chorea is the irregular, jerky, disorderly, incoordinate, purposeless, involuntary movements, which are increased by excitement and are as a rule absent during sleep. They may be confined to one member or to one side of the body, or all of the extremities may be affected. The face rarely escapes. Like the articular involvement of acute

*Read before the Eastern Medical Society, January 19, 1906.

rheumatism, the invasion is usually gradual and progressive. At times the movements attain an extraordinary degree of violence, and they may cause death through exhaustion. Not rarely one or more members are the seat of muscular weakness. Some derangement of cerebral activity is commonly present, and it may assume any grade of severity, from mere irritability of temper to violent mania.

It may be inferred that the symptoms of chorea are brought about by disorder of the motor cells of the cerebral cortex, of bacterial or toxic origin. Under treatment with arsenic, and in the absence of complications, an attack of chorea usually lasts from six to ten weeks. The disease almost invariably terminates in recovery, but occasionally death is the outcome. The latter event may be due to visceral complications, but, as already stated, it may at times result from exhaustion consequent upon the violence of the movements. As in the case of rheumatism, recurrences are common, and they may take place in successive years.

Arsenic appears to act with the efficacy of a specific in the treatment of chorea, and in ordinary cases the administration of Fowler's solution of potassium arsenite, together with good food, ample sleep, fresh air, and freedom from strain and emotional influences, will be sufficient to bring about recovery. Some form of iron may be required in addition, and quinine may be a useful adjuvant. When the movements are violent and the mental perturbation is marked, the patient should be isolated and be kept in bed.

The diagnosis of chorea is, as a rule, easy. Occasionally it is exceedingly difficult. On the one hand the violence of the movements may cause confusion, while on the other hand the presence of paresis may suggest some form of spinal or cerebral or neural palsy. I have seen cases with general convulsive movements and elevation of temperature suggestive of uremia. When mental symptoms predominate care should be taken lest these cause the motor phenomena to be ignored or overlooked.

The term chorea should be reserved for the disorder that has been under consideration, so-called habit-chorea, postparalytic chorea, the various forms of hysterical chorea, and chronic progressive or senile chorea being distinct and differentiable affections.

So-called habit-chorea, or habit-spasm, is better designated spasmodic tic. The disease has no relation to rheumatism, it is unattended with visceral complications, and the duration is variable and indefinite. Whenever I hear that an attack of what is thought to be chorea has persisted for many months, I am at once suspicious of its being spasmodic tic. Moreover, the movements of the two diseases exhibit distinct differences. Those of chorea are often widespread and purposeless, while the movements of spasmodic tic are usually more restricted in distribution, and purposive. The former are somewhat bizarre in character, while the latter, although they may change their seat from time to time, exhibit a tendency to be repeated. It is probably spasmodic tic that has given rise to the fallacious view that true chorea may have a reflex origin, as from eyestrain, the presence of parasites in the intestinal tract, abnormalities of the prepuce in boys and in girls. Neither is spasmodic tic specifically amenable to treatment with arsenic, although tonic medication of any sort is useful here also. The best treatment, apart from that directed to improvement of the general nutrition is hygienic—moral and physical.

The athetoid movements attending various lesions of the brain have a peculiar vermicular character. They do not change their seat, and they are confined to parts usually affected by muscular weakness or paralysis, and often presenting exaggerated reflexes and spastic phenomena. In addition, mental impairment and other signs of cerebral disorganization are likely to be present. The disorder does not respond to ordinary therapeutic measures, although at times the movements can be modified by surgical procedures.

Hysteria may be attended with motor phenomena of a most diverse character, and these may at times closely counterfeit the movements of chorea. The differentiation occasionally is exceedingly difficult, but it will depend essentially upon the recognition of other hysterical stigmata.

The nodding and rotatory movement of the head associated with nystagmus, not rarely observed in rachitic children, may suggest chorea, but it usually occurs at an earlier period of life and is associated with other evidences of rachitis, with the subsidence of which the motor phenomena also subside.

A Case of Sporadic Elephantiasis.—George B. Lake relates the history of this case. The patient was a woman, fifty-six years old, and married, who complained of "dropsy, with a burning discharge from the legs." The family history was negative. The patient was born in northern Indiana and afterward lived in only that State and southern Pennsylvania. She was always very susceptible to the effects of poisonous plants. Nine years ago she had "sloughing ulcers" of the legs, which persisted for two years and finally healed up, as the patient believed, under the influence of a homemade decoction containing potassium iodide, sarsaparilla, guaiac, and various other substances. After the appearance of the ulcers, the legs were somewhat enlarged, and continued to increase in size. The patient denied all possibility of specific infection. The writer, however, believed the trouble to be of syphilitic origin. He therefore put the patient on potassium iodide and mercury internally, giving good-sized doses. Locally, an antiseptic, astringent, and anodyne dusting powder was applied, after the legs were washed with hydrogen peroxide. The further treatment was symptomatic. Treatment, however, proved unavailing. Hard nodules appeared in various places, broke down, and suppurated. They covered both hands, the face, and finally appeared over the whole body. The general strength failed rapidly. As the patient had habitually used morphine in large doses for twenty-five years, this valuable drug was useless in relieving the intense pain from which she suffered. Death finally supervened. The case was one of true sporadic elephantiasis. Unfortunately there was no opportunity for an autopsy.—*The Chicago Medical Recorder.*

Vascular Fasciculated Sarcoma at the Lower Extremity of a Movable Kidney; Lumbar Nephrectomy; Recovery.—Autefage and Danel report this case. The patient was a young woman, twenty-four years old. For five years she had shown symptoms of renal disturbance. Hematuria and pain dated back five years. The appearance of blood in the urine coincided with the crises of pain. For four years pyuria had been present almost continually. Two years later the patient suffered from polyuria. It was at first thought that the disturbance might be due to renal tuberculosis. Operation revealed the presence of a sarcoma. Nephrectomy was performed. The writer draws attention to the long period of evolution of the tumor. The mobility of the tumor was so great that it dropped down as far as the iliac fossa of the same side. The writer believes that such mobility has never been pointed out among the characteristics of malignant tumors of the kidney.—*Le Nord Médical.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE

New York, April 7, 1906.

TYPHOID BACILLURIA.

TWENTY-FIVE years have now elapsed since Bouchard of France made the announcement that in certain proportion of typhoid fever cases the urine contained microorganisms which presented all the morphological characteristics of the germs found in the blood of the same patients. The results published by subsequent observers on this subject showed considerable variation, however, and cannot be regarded as accurate, because it was not until 1895 that Escherich discovered *Bacillus coli communis* and separated it from *Bacillus typhosus,* and only in 1896 did Widal announce his method of separating Eberth's bacillus from the colon group. Since that time considerable progress has been made in the bacteriology of typhoid fever, and greater attention is now accorded to the urine as an important factor in the dissemination of the infection. But even during these later years much diversity of opinion exists as to the frequency of bacilluria in typhoid fever, and estimates vary from 20 to 53 per cent. The latter figure is given in the most recent work on the subject, an investigation conducted by R. D. Brown of Edinburgh, published in the *Edinburgh Medical Journal* for February, 1906, which is distinguished by very careful laboratory examinations of the urinary secretion in a number of typhoid cases. This fact will probably account for the large proportion of positive results.

A number of theories have been advanced to explain the presence of the typhoid bacilli in the urine, none of which, however, is quite satisfactory. The most adequate seems to be that one or two stray bacilli manage in some way or other to pass through the kidney from the blood, and after they get into the urine to grow very rapidly. It has been experimentally proven that this fluid is a good medium for the growth of *B. typhosus,* and another favorable condition is found in the suitable temperature of the bladder. This theory seems also confirmed by the circumstance that vesical irrigations with germicidal solutions rapidly bring about the disappearance of the organisms from the urine.

From observations thus far published it seems quite safe to assume that *B. typhosus* exists in the urine of typhoid patients in from 30 to 35 per cent. of the cases. No outward symptoms of this condition may be manifested, and, although albuminuria and pyuria are frequent accompaniments, they are by no means necessary concomitants. A bacteriological examination seems to be the only means by which the presence of the typhoid bacillus can be ascertained, and this should be made a matter of routine.

Considerable diversity of opinion exists as to the time of the appearance of the organism, and, as no rule can be formulated, it is wise to regard the urine with suspicion from the very beginning. It has been shown that the typhoid bacillus frequently disappears from the stools at an early date and its place is taken by the colon bacillus. The feces are therefore no longer a factor in the spread of the disease comparable in importance with the urine, for the soiling of the patient's surroundings by the latter is much more apt to escape notice than that by fecal matter. This occurs not only during the time when the patient is still confined to his bed, but also during the period of convalescence when he is up and about and apparently cured. Pollution of the water supply is also more apt to occur through urination than by defecation.

The author's recommendations include, aside from the usual precautionary measures, the disinfection of the urine and the administration of a urinary antiseptic. He advises that all typhoid patients, at whatever stage of the disease, should micturate into special receptacles, which, together with their contents, may be disinfected. In addition, he advocates the administration from the third week on of hexamethylenamin in ten-grain doses three times a day for ten days, and after a week's interval this should be repeated for a similar period. The effect must, of course, be checked by bacteriological examinations of the urine at frequent intervals. With this knowledge at hand, and the ready means which we possess for combating such a source of danger, it seems almost criminal to neglect the precautions just referred to when treating a case of typhoid fever.

MORPHINE-SCOPOLAMINE NARCOSIS.

ALTHOUGH the introduction of general anesthesia by the inhalation of ether or chloroform has been quite generally accepted as one of the greatest medical discoveries of the last century, the disadvantages which have been found to attend its use have been the means of prompting a constant search for satisfactory substitutes. It has been sought to overcome the unpleasant features associated with the inhalation methods by the subcutaneous administration of various narcotic substances, and among those which have received the greatest amount of attention during recent years are the two alkaloids, morphine and scopolamine in combination. Schneiderlin first suggested their employment in 1900, and since that time the method has been subjected to a sufficient period of probation to permit of drawing certain conclusions. Among the more extended applications may be noted their use in a series of one hundred gynecological cases of greater or lesser import, recorded by Karl Voigt in the *Monatsschrift für Geburtshülfe und Gynäkologie,* December, 1905.

There are certain peculiarities associated with anesthesia in gynecological cases which render the ordinary methods undesirable in many instances. Narcosis may be required merely for an examination or exploratory operation, necessitating another anesthesia within a comparatively short period; the patients are very often in a poor general condition: the extent of the operative procedure and its vital import oftentimes bear no relation to the danger associated with inhalation narcosis, and the large proportion of

laparotomies in this class of cases demands an anesthetic which will produce little tendency to retching or vomiting. Gynecological operations would therefore seem to afford a good test for the purpose of trying a new method of narcotization. Judging from Voigt's results in this large series of unselected cases, the millenium, in this regard at least, has not been reached. One of the most noteworthy features of the report is the statement that morphine-scopolamine anesthesia alone is insufficient for extended operations; in only six cases out of the hundred was it possible to finish the operation, although only slight in extent. In others, again, to the number of fourteen, no effect whatever was obtained, and in thirty-two unfavorable sequelæ were noted. These results are not encouraging, and yet there seems to be a field for the method, for it may apparently be employed to advantage as a preliminary to etherization by the drop method, as it produces a more marked quieting influence than the use of morphine alone, inhibits the action of the secretory nerves to the salivary and mucous glands of the mouth and upper air passages, allays vomiting and excitement, and permits the quantity of anesthetic needed to be diminished. It is recommended, however, that the dosage be as small as possible—less than that ordinarily employed, in order to avoid any possible after-effects of an unpleasant character. This dose is 0.0005 gram scopolamine hydrobromate and 0.01 gram morphine hydrochlorate.

The weak point in the method is its unreliability, for it is impossible to predict how this combination of drugs will react in any given case. The reason for this resides mainly in the fact that the composition of scopolamine is very inconstant, since this is made up of a mixture of various isomeric alkaloids which have thus far resisted all attempts at isolation. If a preparation of scopolamine can be obtained with a definite composition, it may then be possible to find the reason for the idiosyncrasies which have been observed, and thus to formulate indications and contraindications for the use of the drug. At the present time, however, the method is surrounded by too many uncertainties to warrant its general adoption as an efficient substitute for inhalation narcosis.

THE TOXEMIAS OF PREGNANCY.

The importance accorded to certain toxemias as etiological factors in the production of disease has been gradually extended from year to year, and foremost among them in point of interest are those toxic states associated with pregnancy and which have now come to be the regarded as one, if not the only, cause of hyperemesis, acute yellow atrophy, eclampsia, and similar pathological conditions complicating this physiological process. This view is, moreover, apparently corroborated by clinical observations and laboratory research, although there are not as yet sufficient data at hand to warrant attributing all these conditions to one poison or to one variety of faulty metabolism. Experimental efforts have been made to isolate these toxins, but the success attained is far from complete or uniform. In a recent contribution to the subject F. E. Sondern (*Bulletin of the Lying-In Hospital*, New York, December, 1905) calls attention to the fact that the literature on this subject deals largely with the changes found in the nitrogenous metabolism, and thus lends color to the belief that these changes are the cause of the clinical symptoms. There are certain poisons, however, such as phosphorus, which bring about a similar hepatic change, with a disturbed nitrogenous metabolism, but with no semblance in the way of clinical manifestations. Then there are cases of diabetes which show as relatively high a percentage of ammonia, and some of erysipelas which are accompanied by an equally large amount of amido acids in the urine as may be found in the hyperemesis of pregnancy, yet neither of these ailments is characterized by vomiting as a marked symptom. It therefore remains for a poison to be found to which may be attributed the symptoms as well as the pathological changes and impaired metabolic processes associated with these disturbances of pregnancy.

In the absence of a knowledge of the direct causative factors in the toxemias of pregnancy there are a number of abnormal conditions in the urine which, according to the writer, afford corroborative evidence in diagnosing the condition and which may aid in forming an opinion as to its severity. These are the usual evidences accompanying an intestinal toxemia, namely, an excess of indican, skatol, phenol, or, more properly speaking, increased relative amounts of the ethereal sulphates. The occurrence of acidosis, as shown by the presence of aceton, diacetic acid, and beta-oxybutyric acid, affords the earliest indication of the presence of a toxemia in pregnancy, the severity of which corresponds quite accurately to the appearance of these in the order named. Symptoms preceding eclamptic seizures of toxic origin show the same conditions, and in either case, if the conditions become still more serious and liver changes are added, then, and not until then, are the alterations in nitrogenous metabolism obtained. Dr. Sondern's observations clearly show that the analysis of the urine in pregnancy constitutes one of the most important duties devolving upon the attending physician, and particularly, when even slight disturbances of the general health are noted by the patient, the examination should include the tests for the evidences accompanying intestinal toxemia as well as those for acidosis. The routine determination of albumin, sugar, and casts can no longer be regarded as sufficient, and the false sense of security afforded by the absence of the former is only too often followed by an unlooked-for and sometimes fatal issue.

Poor Consumptives in the West.

The Medical Record has already on numerous occasions discussed the necessity for individualization in deciding the matter of climatic treatment in pulmonary tuberculosis. It is not alone the patient's bodily condition, but the physical state of his pocketbook as well which must be regarded in considering whether or not to send him away from home, and if so, where. The importance to the patient of good food, properly prepared, and of conditions favoring mental equanimity and providing for a sufficiency of physical repose is now well understood, but these desiderata are unattainable by a sick person who leaves home inadequately provided with funds which he must husband from the start, and who soon finds his slender resources dwindling to the vanishing

point. The western communities elected as resorts by the majority of tuberculous Easterners are being obliged to contribute largely to the support of indigent strangers, and the burden is one that it is unjust to impose upon them. A warning has already been circulated by some of the Arizona towns, and the Charity Organization Society of Denver is at present distributing to physicians a circular letter pointing out the hardships that await sick people devoid of financial resources with half the continent between them and their friends. In this circular it is stated that Colorado, like other health resorts, is flooded with patients with tuberculosis who have been mistakenly sent there. It should be understood thoroughly that no patients should be sent there who have not sufficient means, or for whom provision has not been made, to live in comfort and without worry for from six months to two years. If the patient has even one degree of temperature daily he cannot be expected to recover without almost absolute rest, in bed most of the time, until this subsides. Owing to the number of invalids who go there, suitable employment is much harder to obtain than in Eastern communities. If one has about him any of the marks of invalidism, even if it be but an occasional cough, his chances for employment are much damaged. The substance of this whole matter is that patients with tuberculosis should go West only upon the advice of some physician particularly expert in chest diseases; should go only during the first few weeks, or possibly months, of the disease, if recovery is to be expected; should have sufficient provision made to live without work or worry for a year, at least in most cases; and should be under the guidance of a well-qualified physician after arrival.

The Leucocyte Count in Cases of Pneumonia in Childhood.

The appearance of an increased number of leucocytes in the blood in connection with various infectious processes must be considered as the expression of a biological or chemical reaction induced by the toxins generated in the course of the given disease. Such leucocytosis is not invariably present in all forms of infectious disease, and it may occur, besides, as the result of intoxication of other origin, and also of such physiological activities as the digestive process. During the first few years of life the number of leucocytes in the blood is normally greater than in adults, while variations occur more readily and are more marked than in later life. A study of the leucocyte-number in twenty-four cases of croupous pneumonia, nineteen cases of bronchopneumonia, and seven cases of empyema in children, made by Drs. Henry Heiman and Henry Koplik (*Archives of Pediatrics*, October, 1905), has yielded interesting results. A well-marked leucocytosis was found in the cases of bronchopneumonia, independently of the amount of lung involved and of the temperature. As a rule, not without exception, failure of the leucocyte-count to fall when the physical signs of the pulmonary disorder disappear indicates either a complication or a fatal termination. A constant and considerable leucocytosis was found in the cases of fibrinous pneumonia. The degree of leucocytosis was about the same in the two forms of pneumonia—an average of 33,900 for the cases of bronchopneumonia and 31,700 for those of fibrinous pneumonia. In the cases of croupous pneumonia the leucocytosis was proportionate to the extent of the pulmonary involvement, but there was no relation to the temperature. An increasing leucocytosis was the rule in the cases of croupous pneumonia, reaching the maximum just before the crisis. Failure of a decline to take place in the number of leucocytes may or may not indicate the occurrence of a complication. There was no precritical fall constantly, and this phenomenon proved of little or no prognostic value, and without significance as related to the time of crisis. Empyema was attended with high leucocytosis at the onset. The conclusion is reached from the observations made that the diagnostic value of leucocytosis in the pulmonary affections of children is limited, although in certain instances or under certain conditions the leucocyte count may be of great diagnostic aid. Thus a sharp rise in the leucocyte count after resolution and decline in the leucocytosis have occurred in the course of an attack of croupous pneumonia should arouse suspicion of empyema, especially in the presence of physical signs and symptoms indicative of that condition.

News of the Week.

The Centennial Celebration of the County Medical Society. — A dinner was given at the Hotel Astor on Wednesday evening of this week to celebrate the one-hundredth anniversary of the incorporation of the Medical Society of the County of New York. The first meeting of the Society was held on November 14, 1794, but it was not until April 4, 1806, that the Legislature passed the law under which the Society was incorporated. Over two hundred members and invited guests took part in the celebration. Dr. Floyd M. Crandall, President of the Society, acted as toast-master. Toasts were responded to as follows: "The Medical Society of the County of New York," by Dr. William M. Polk; "The Medical Society and Its Responsibilities to the City," by Hon. John J. Delany, Corporation Counsel; "The Church and the Medical Profession," by Rev. Dr. Charles P. Fagnani; "Law and Medicine," by Hon. Job E. Hedges; "The Medical Society of the State of New York and Its Relations to the State and County," by Dr. Samuel B. Ward of Albany.

Society of Sanitary and Moral Prophylaxis.— A meeting of this society will be held at the Academy of Medicine in this city on Tuesday, April 10, at 8:30 P. M. Papers will be presented by Dr. John A. Wyeth, Dr. John A. Fordyce, and Hon. William Lindsay.

Seaside Hospital Fund.—An anonymous donor has contributed $25,000 to the New York Association for Improving the Condition of the Poor, to aid in the building fund for the first American Seaside Hospital for Crippled Children. The hospital is to be built as soon as the association has secured the necessary $250,000, toward which sum John D. Rockefeller has given $125,000 with a proviso that the entire amount must be raised before July 1. During the past week the association has also received contributions amounting to $30,000 from seven other donors.

Ordinance Regulating Storage Plants Favorably Recommended.—Health Commissioner Whalen of Chicago has secured from the Judiciary Committee a favorable recommendation of the ordinance to regulate cold storage plants. The ordinance, which places the plants in which food products are stored under the supervision of the health officials, will soon go to the Council. Its provisions are: Warehouses to be licensed after they have proved on inspection to be in a sanitary condition. Poultry and fish to be drawn before being put in storage. Foods must be tagged with date of re-

ceipt and shipment; tags to remain on original packages when goods are sent out. The city must be notified when any articles have been in storage six months; the inspector then will visit the warehouse to see if the food is still fit for use and condemn it, if it is not so.

For a Monument to v. Mikulicz.—An international committee has been formed to solicit and receive contributions for a monument in honor of the late distinguished surgeon, Johannes von Mikulicz-Radecki of Breslau, Germany. The American members of this committee, Drs. W. W. Keen of Philadelphia, W. S. Halsted of Baltimore, J. B. Murphy of Chicago, and F. Kammerer of New York, appeal to the surgeons of the United States and Canada for subscriptions to the fund. Contributions may be sent to any member of the committee.

Philadelphia Hospital. — The Councils of the City of Philadelphia have appropriated the sum of $49,000 to the Department of Health and Charities for alterations to the Philadelphia Museums buildings, boilers, internal improvements, and the removal of the exhibits, as part of the plan to improve the conditions at the Philadelphia Hospital.

A Testimonial to Dr. Boas.—At the close of the coming summer Dr. J. Boas of Berlin will have reached the twenty-fifth anniversary of his graduation in medicine and will also terminate his polyclinical connection, after twenty years of service. A committee of his friends and pupils have planned to present him at this time with an artistically executed address, which shall bear the names of those who help to contribute the necessary funds by sending the sum of 6 marks to the treasurer of the committee, Dr. Eugen Lilienthal, Berlin, W. Kleiststrasse 15.

A Gift to the Peabody Museum.—Dr. T. Mitchell Prudden, Professor of Pathology in Columbia University, has presented to the anthropological section of the Peabody Museum of Natural History at Yale University the archeological collections made by him in Southern Utah, Southern Colorado, New Mexico, and Arizona. The collection comprises textile fabrics, pottery, ornaments, etc., of the cliff dwellers and Pueblos, as well as valuable maps and field notes.

New Illinois Hospital. — A hospital that will cost $100,000 will be erected at the northeast corner of Wisconsin Avenue and Monroe Street, Oak Park, Ill., for the Sisters of Miserecordia. The structure will be five stories, 45x125 feet.

Illegal Use of a Name.—The Branch Appellate Court of Chicago has decided that the so-called Christian Hospital must pay a fine of $250 for the use of the name of Dr. John B. Murphy of Chicago without permission. This decision is the result of proceedings brought by Dr. Murphy, who secured an injunction restraining the defendants from using his name. In May, 1903, Dr. Murphy received a letter from the president of the hospital, informing him he had been elected President of the Medical and Surgical staff of the institution. Dr. Murphy had never heard of the institution, and refused to have anything to do with it.

Hospital for the Treatment of Acute Alcoholism.—An ordinance in the Chicago City Council has been introduced by Alderman Scully, providing for the construction and maintenance of a hospital for the treatment of acute alcoholism.

Dr. Nicholas Senn of Chicago was recently elected an honorary member of the Imperial Royal Medical Society of Vienna.

Free Alcohol Bill.—On March 30 the Committee of Ways and Means by a vote of sixteen to two authorized a favorable report on the bill intended to remove the internal revenue tax from alcohol for use in the arts and sciences which has been denaturized in such a way as to make it unfit for consumption as a beverage. The bill provides that, beginning three months after its passage, domestic alcohol of such degree of proof as may be prescribed by the Commissioner of Internal Revenue and approved by the Secretary of the Treasury may be withdrawn from bond without the payment of internal revenue tax, for use in the arts and industries, and for fuel, light, and power, provided it shall have been mixed in the presence and under the direction of an authorized Government officer before withdrawal with denaturing material suitable to the use for which the alcohol is withdrawn, but which destroys its character as a beverage and renders it unfit for liquid medicinal purposes. The sale of denaturized alcohol as a beverage or for liquid medicinal purposes is forbidden by the measure under penalty of fine not to exceed $5,000 or five years' imprisonment, or both, in the discretion of the court. It is estimated that the annual loss in revenue will not exceed $500,000, while the advantages to the country will be very great.

Dr. Henry Sykes, formerly medical superintendent of the Episcopal Hospital, Philadelphia, has been temporarily appointed chief resident physician, pending a civil service examination.

For Clean Prisoners.—A wholesome reform is projected by the Board of Magistrates, who have recently appointed a committee to try to induce the Board of Health to arrange for the washing and disinfection when necessary of disreputable prisoners, who at present are brought into the courtroom in their habitual filthy condition.

Civil Service Examinations.—Among the positions for which the State Civil Service Commission will hold examinations on April 14, 1906, are the following: First Assistant Physician, State Hospital for Tuberculosis, $1,500 and maintenance; Medical Superintendent, State Hospital for Tuberculosis, $3,500 and maintenance for Superintendent and his family; Physician, Westchester County Jail, $400; Trained Nurse, State Institutions, usual salary $420 and maintenance. The last day for filing applications is April 9. Application forms and detailed information may be obtained by addressing Mr. Charles S. Fowler, the Chief Examiner of the Commission, at Albany.

Less Beauty in China.—Chinese esthetes will no doubt be grieved by a recent action of the Pekin Board of Education, which, in an endeavor to stop the practice of foot binding, has issued an edict prohibiting the sale of the special shoes used by the victims of the measure.

Antituberculosis League in Porto Rico. — An antituberculosis league has been organized in Porto Rico under the auspices of the Administration and many prominent natives and Americans. A large number of subscriptions have already been received.

Dr. Herman M. Biggs, chief medical officer of the Board of Health, is to leave shortly to make a three months' official tour of inspection of the European hospitals and water filtration plants.

Vaccination in Paterson.—As a result of their refusal to submit to vaccination, twenty teachers and several hundred pupils of the Paterson, N. J., public schools have been suspended. Many of the

teachers who have been vaccinated have been obliged to stay at home on account of illness, so that the entire list of substitute teachers has been exhausted, and it is expected that further vacancies will occur.

One Health Board Sufficient.—Health Commissioner Darlington has been opposing the bill seeking to create a separate Department of Health for the boroughs of Brooklyn and Queens, on the ground that such a measure would entail a policy of decentralization, confusion in administration, increased expense, and lessened efficiency.

Ambulance Chasing.—A strong effort is being made at Albany by the adherents of the Wemple bill to secure the passage of this measure, which is intended to break up the practice of the professional ambulance chasers. Bills similar to this one have already been passed in Massachusetts, Maryland, and other States, and are expected to reduce the number of accident frauds.

Yellow Fever at New Orleans. — It was found at the autopsy of a patient in the New Orleans Charity Hospital whose illness had been diagnosed by several experts as yellow fever, that the cause of death was an affection of the liver accompanied by jaundice. In order to allay all doubt the heads of the Health Boards of several neighboring States were invited to be present at the post-mortem examination. At a meeting of the Orleans Parish Medical Society held on March 21 resolutions were adopted urging physicians to report at once any suspicious cases and providing that any member of the society who failed to do so would be held guilty of unprofessional conduct and be tried for the offense by the society's judiciary committee.

The Sacramento Society for Medical Improvement, at its annual meeting, completed its thirty-eighth year, as it was organized March 17, 1868. The officers elected for the coming year are: *President*, Dr. H. R. Wright; *Secretary and Treasurer*, Dr. E. M. Wilder.

The Atlantic Coast Line Surgeons, at their annual convention held at Tampa, Fla., on March 21, elected these officers: *President*, Dr. D. W. Bullock of Wilmington, N. C.; *Vice-President*, Dr. W. P. Adamson of Tampa.

The Homeopathic Medical Society of Western Massachusetts, at its annual meeting held in Springfield on March 21, elected the following officers: *President*, Dr. Robert F. Hovey of Springfield; *First Vice-President*, Dr. E. P. Bixby of Barre; *Second Vice-President*, Dr. H. C. Cheney of Palmer; *Secretary and Treasurer*, Dr. James B. Comins of Springfield.

The Sydenham Medical Library has recently been established for the benefit of tenants in the Sydenham medical office building. Dr. Mark J. Knapp is the librarian.

Dr. Charles Warrenne Allen has been appointed the delegate of the American Dermatological Association to the Fifteenth International Congress, to be held in Lisbon April 19 to 26.

Dr. Augustin H. Goelet of New York was the guest of the Harrisburg Academy of Medicine Friday evening, March 30, when he presented a paper entitled "Posterior Displacements of the Uterus that Are Curable Without Operation."

City Death Rate Going Down.—Health Commissioner Darlington announced yesterday that, despite the largely increased population, the death rate for March was 20.83, while in March, 1905, it was 21.17. The total number of deaths last month was 1,633, as against 1,658 in March, 1905.

The Second International Congress on School Hygiene will be held in London from August 5 to 10, 1907, the President being Sir T. Lauder Brunton.

Obituary Notes.—Dr. Allen H. Oliver of this city died suddenly of apoplexy on March 27, at the age of fifty-eight years. Dr. Oliver was born in New Orleans and spent a considerable portion of his early life in Europe. He served through the Franco-Prussian War in the Garde Mobile, and on his return to this country took up the study of medicine, being graduated from the medical school of the University of Pennsylvania in 1882. He practised in this city for about fourteen years, and for the past eight years had been assistant superintendent of the Presbyterian Hospital.

Dr. James W. Smith of Paterson, N. J., died on March 29, at the age of forty years. He was appointed physician to St. Joseph's Hospital in Paterson in 1883 and had been on the visiting staff ever since. He was president of the Board of Managers of the State Hospital for the Insane, and assistant health officer of Paterson.

Dr. Seth Cook Comstock died in this city on March 27, at the age of thirty-five years. He was born in New London and received the degree of M.D. at the New York College of Physicians and Surgeons in 1893. In 1901 he removed to Wimbledon, Eng., where he devoted himself to literature.

Dr. George S. Dearborn of Rockaway died of pneumonia on March 26, at the age of seventy-one years. Dr. Dearborn was born in Winthrop, Me., and was a graduate of the Albany Medical College. He served as a surgeon in the Civil War and had practised in Rockaway since 1889.

Dr. William J. Mahon of this city died on March 27 in Hartford, Conn., at the age of thirty-three years. He was graduated from the Bellevue Hospital medical school nine years ago and had made a specialty of diseases of the eye and ear. He was a lecturer at the New York Polyclinic and surgeon to the Metropolitan Throat Hospital.

Dr. James M. Boyd of Walla Walla, Wash., died on March 20, at the age of sixty-nine years. Dr. Boyd was born in Kentucky, and he first practised in Iowa, moving West in 1865. In 1878 he removed from Baker City to Walla Walla, where he had practised ever since. He served several terms as City Health Officer and in 1886 he was elected Mayor.

Dr. J. C. Le Grande of Birmingham, Ala., died on March 21, at the age of fifty-two years. Dr. Le Grande was a native of Alabama and was graduated from the Atlanta Medical College in 1880. In 1887 he removed to Birmingham and at various times he had been vice-president of the American Medical Association, president of the Tri-State Medical Association of Alabama, Mississippi, and Georgia, and president of the Alabama State Medical Association. He founded the *Alabama Medical Journal*, of which he was the editor for eighteen years.

Dr. J. G. Gilchrist of Iowa City, Ia., died on March 20, at the age of sixty-four years. He was born in New York City and was graduated from the Homeopathic Medical College of Pennsylvania. He practised first in Minnesota and in Michigan, and in 1883 removed to Iowa City. He was well known as a surgeon and was the author of nearly a dozen different works on medical and surgical subjects. He was a member of numerous homeopathic societies and had held office in many of them.

Dr. George Sullivan Woodman of Newtonville, Mass., died on March 22 in Cambridge, Mass. Dr. Woodman was born in Boston in 1824 and was graduated at Amherst in 1846 and at the Harvard Medical School in 1849. During the Civil War Dr.

Woodman was an examining surgeon and was stationed at Brooklyn. He was a member of the Massachusetts Medical Society and later of the Massachusetts Homeopathic Society.

Dr. THOMAS F. RICHARDSON of the United States Public Health and Marine Hospital Service died in New Orleans on March 19, of typhoid fever, at the age of thirty-four years. Dr. Richardson was born at St. Joseph, La., and received his medical degree from the Tulane Medical College in 1898. He entered the United States Public Health and Marine Hospital service in 1899 and at the time of his death was passed assistant surgeon.

Dr. GEORGE G. WISE died at Philadelphia on March 27, at the age of sixty-one years. He was graduated from the medical department of the University of Pennsylvania in the class of 1866.

Dr. ROSCIUS Y. DOWNS of Ansonia, Conn., died on April 1, at the age of forty-eight years, as the result of an infection received while operating.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS AND OUT-PATIENT EXPENSES—AMALGAMATION OF SOCIETIES—TUBERCULOUS PLEURISY—TRAUMATIC DIABETES—CARRYING INFECTION—AMBULANCE FIELD WORK—LEGISLATION FOR NURSES—X-RAY INJURIES—AN AMBULANCE SERVICE—OBITUARIES.

LONDON, March 16, 1906.

THIS morning comes an appeal for £120,000 to pay off the debt and annual deficit of Charing Cross Hospital. Yesterday a meeting to help was held in His Majesty's Theater, kindly lent by Mr. Beerbohm Tree. It was stated that 2,500 in-patients are treated in a year and 20,000 to 21,000 out-patients. The origin of the trouble was acknowledged to be the great rebuilding scheme, the cost of which, as so often the case, has greatly exceeded the estimates. It was said that if hospitals were thrown on the rates they would cost more, which is likely enough, but that is a poor excuse for the extravagance and rashness of hospital managers. No one suggested that the out-patients' department of this hospital might be closed without any hardship to the sick poor of the neighborhood, and that all the money spent on this department might have been saved and attached to the other buildings.

The 133d anniversary of the Medical Society of London was celebrated last night by the usual dinner. This society was originally a sort of offshoot of the Royal Society, a beginning in a way of specialism when medical subjects became too numerous for the great scientific body to cope with. During its existence the "old medical" has seen the rise and progress of other societies, not a few of them instances of further specialization. This furnished the president with a subject, and he talked of the advantages and disadvantages of specialism in the profession.

The question of amalgamation of the societies was bound to come up, and Dr. Donald MacAlister, president of the General Medical Council, took it up in proposing the toast of the evening. He congratulated the members that they supported the movement, on the ground that general medicine should have a full voice and adequate vote in the constitution of the proposed academy. I made remark on this that it remained to be seen whether satisfactory financial arrangements could be made. This society, for instance, is prosperous, its financial position assured, for it is saving about £400 a year, and its total debt is only about £2,500, so that every year it is growing stronger financially.

A general meeting has not yet been called to consider the scheme for union, but it is probable, when held, that the proposal will be accepted.

At the ordinary meeting of the society Dr. Sidney Martin contributed a paper on tuberculous pleurisy. He was doubtful concerning the older facts and the opinions deduced from them as to the relative frequency of simple and tuberculous pleurisy, and thought examination of the fluid would give more trustworthy data. A case of primary pleurisy may be due to the pneumococcus, streptococcus, staphylococcus, or to the tubercle bacillus, *i.e.* it may be tuberculous or non-tuberculous, and the distinction is clinically of the highest importance, but may be very difficult to make. The diagnosis must be made from the (*a*) mode of onset, (*b*) course, and (*c*) after-effects on chest wall and lung. The onset may be sudden in either case. Latent cases were almost invariably tuberculous. Unilateral deficiency of movement Dr. Martin regarded as a valuable sign in early diagnosis. Recurrent cases also were almost always tuberculous; non-tuberculous cases tend toward recovery. Dry pleurisy may run a short course with slight pyrexia and leave no deformity of the chest wall, even though the effusion may be considerable. The fluid, if removed at an early stage, will coagulate spontaneously. By centrifugalizing about 100 c.c. the deposit, on examination, will be found to contain one or more of the cocci above mentioned. If sterile, it will indicate tuberculous pleurisy, and the course of the disease will be different, the acute stage long, recovery, if it occur slow, followed by deformity of the chest from contraction of the lung—"pleurisy with retraction." In some of these cases there may be no effusion, but they come on insidiously and last long, commencing with slight pyrexia, some friction sound usually in the lower part of the axilla. Weak breathing will soon be noted without crepitation, increasing dullness, due to thickening or fibrosis of the pleura, will succeed, evening rise of temperature continuing; but for certain diagnoses it will be necessary to puncture the pleura and ascertain the absence of pus.

Tuberculous cases with effusion also present difficulties in diagnosis. In them the pyrexia is often prolonged, and in the absence of empyema may last for weeks or months. The effusion will recur after withdrawal, necessitating a second or third paracentesis, sometimes even a more frequent tapping, on account of firm adhesions having formed a pocket in which the fluid is kept. This fluid must be examined bacteriologically and microscopically to confirm the diagnosis; cases of pleurisy with expectoration should be diagnosed by examination of the sputum.

As to treatment, Dr. Martin advised removal of the fluid in the acute stage when it was large in quantity and showed no signs of absorption, for, apart from urgent symptoms, adhesions are likely to occur if the case is tuberculous. For cases running a prolonged course without urgent symptoms he recommended lying in the open air, well wrapped up and well fed. Even after pyrexia ceased he advised long open-air treatment to help heal tuberculous lesions, and said if this were systematically practised it would, to a great extent, prevent second attacks of tuberculosis, which so often affect the lungs and lead to very chronic illness, or more immediately to death.

Dr. Theodore Williams said more cases of pleurisy were tuberculous than was generally supposed. Dr. Hector Mackenzie's statistics showed about a third to be so. Recurrence was evidence of tuberculous pleurisy, but such cases might clear up quickly for a time. Dry pleurisy was always suspicious.

Dr. Chapman inquired as to the value of *x*-ray examinations.

Dr. Samuel West commented on the relative frequency of simple and tuberculous pleurisy, the significance of rapid disappearance of the effusion and the rapidity with which the fluid coagulated when withdrawn.

A man of 44 was exhibited at the Clinical Society last Friday, who, five years ago, was thrown from his bicycle and made unconscious for fourteen days, fluid dripping from the nose. On becoming conscious bilateral temporal hemianopia and ocular paresis pointed to fracture of the base of skull. Afterwards he had extreme polyuria and thirst without sugar or albumen. No sugar could be made to appear by diet arranged for the purpose, but two years later glycosuria appeared spontaneously, diminished but not quite prevented by careful dieting. Traumatic diabetes is not very common, and the succession of the two forms is rare. It was remarked that traumatic glycosuria does not usually last after the reservoirs of glycogen are emptied.

Dr. Herbert French, who, with Mr. Ticehurst, related the case, said, in reply to a question, that there were two cases on record with similar localizing brain symptoms. It had been suggested that the polydipsia and polyuria might be secondary to injury of a hypothetical "thirst center." Dr. F. Buzzard and Mr. I. Cunning then read a paper on a case of post-traumatic hemorrhage from the superior longitudinal sinus without fracture of the skull; recovery after operation. On April 1, 1905, a man of 25 fell on the back of his head, causing a slight wound, which healed easily. A fortnight later continuous increasing headache came on, and in a few days complete left hemiplegia and hemianesthesia, with stupor, slow pulse, and vomiting, but no optic neuritis. He was trephined on the 18th of April over the right post-parietal region. A large accumulation of blood was under the dura mater and rapid hemorrhage from the neighborhood of the superior longitudinal sinus. Forceps were applied to the bleeding point and a saline infusion was given. On the 30th the forceps were removed; the paralytic condition had improved, and progress went on to complete recovery. The rarity of hemorrhage from this part without fracture of the skull was referred to, and Mr. Gould remarked that he saw Mr.

Heath operate successfully on such a case in which, however, there was no paralysis.

A suit against two medical men was decided in their favor last week. Damages were claimed for the alleged conveyance of scarlet fever to a patient attended in her confinement by one of the partners. It was stated that he told the husband he was not attending infectious cases at the time, although not long before he had had a case of scarlet fever. All antiseptic precautions being taken, the risk must be slight, but in any case if a doctor should be held liable in damages whenever one of his patients fell sick with an infectious disease it is obvious he would have to decline attendance on such cases and then—what?

The London Volunteer companies of the R. A. M. C. and of the Electrical Engineers engaged in practical maneuvers one night lately on Wimbledon Common. It was assumed a battle had been fought, and the medical corps and ambulances set to work to pick up the wounded, many of whom had crept into the coppices and among the bushes. A large marquee was pitched for a dressing station, ambulance wagons sent forward for a collecting station, searchlights swept round and into the woodland, and parties pushed on to give first aid and then to help the wounded into the wagons. A couple of dogs trained for ambulance work searched the remoter area. The maneuvers were witnessed by a few interested spectators, and were said to give a good idea of ambulance duty on the night after a battle.

Nurses are not by any means agreed about the proposals for legislation in their interests. Even those who advocate registration cannot agree upon the terms or method of carrying it out. At a meeting last week their differences were acutely accentuated. Mrs. Fenwick declared that fair treatment could not be obtained at such a whipped-up meeting, and no notice would be taken of its doings. There was quite a scene respecting the number of doctors to be placed on the Central Board. Nurses, some said, would not submit to be governed by doctors. One of them asserted that doctors sent women out as nurses whose characters would not bear examination, and would put them on the register, and she refused to retract this shameful charge. Dr. Thorne told them doctors would not accept a subordinate position. One nurse said she would rather be governed by doctors than by such excited women as had been speaking. Sir J. Crichton-Browne (in the chair) remarked that doctors might not be so anxious as some supposed to serve.

An action was brought against a firm of chemists for alleged negligence in the application of *x*-rays. The defense was that the chemists did not profess to be experts in therapeutics, but used their skill in the mechanical use of the rays only under the directions of the doctor. A large amount of expert evidence was called as to whether it was possible to prevent burning, and further as to whether the *x*-rays were suitable for the case. On both these questions there were contradictory assertions. At the conclusion of the case the jury spent more than an hour in considering their verdict, and then announced there was no hope of their agreeing. They were discharged. Does not this case show that treatment by *x*-rays as by electricity and other means should be carried out by the prescribers?

St. Bartholomew's Hospital is prepared to supply stabling and a surgeon to the proposed horse-ambulance, to be established under the charge of the city police. The corporation contributes toward the city police service, and the combination of the ambulance with it would no doubt be more effective and less costly than under other control.

Mr. W. Falconer Clark died at Dorking, where he practised many years. He began his professional career in the Old East India Company and served on the North-west Frontier and through the mutiny. He was present at the siege of Delhi and the relief of Lucknow, and obtained two medals and four clasps.

Francis J. Crane Parsons, J. P. of Bridgewater, who died on Saturday, was a very active worker in public matters as well as in the profession. He was an able Medical Officer of Health and Port Sanitary authority, and Senior Surgeon to the local infirmary, and held other appointments. He took the double qualification of the London Colleges in 1871, when his age was thirty-three, as he began medical study rather late.

Swallowed Foreign Bodies may, according to Blair Bell, be rendered harmless in their passage through the intestine by the administration of a quantity of absorbent cotton plucked into small shreds and given in bread and milk. The foreign body becomes enveloped in the shreds of cotton so that any sharp angles are covered over and injury to the intestine is avoided.—*Medical Press and Circular.*

OUR PARIS LETTER.

(From Our Special Correspondent.)

EMIGRANTS FROM THE EAST—THE FIGHT AGAINST TUBERCULOSIS—HYDATID CYSTS OF THE LIVER—SERPENT VENOMS—THE DEATH OF DR. DE WECKER—CRUISE TO THE LISBON CONGRESS.

PARIS, March 7, 1906.

At the Académie de Médecine, Chantemesse and Borel pointed out the desirability of supervising the emigration of Orientals in order to protect public health by subjecting the emigrants to rigid surveillance. About 60,000 emigrants, coming from Asia Minor, Arabia, and Egypt, pass through France every year in order to embark at Havre for America. Up to the present time no sanitary precautions have been taken against these transient guests, some of whom might be dangerous and might bring in with them the germs of cholera. Therefore Chantemesse proposed that the Académie should draw up a resolution urging legislation to be enacted regarding the entrance of emigrants into France, and their passage through the country; that these regulations should be founded on the measures in force in other countries, and that the sanitary surveillance of the emigrants should be carried out by a special department. The resolutions were unanimously adopted by the Académie.

A very interesting discussion on the struggle against tuberculosis was also held at the Académie de Médecine. Professor Robin, who first brought up this topic for discussion, expressed the opinion that the mortality statistics of tuberculosis should be obtained more generally and in a more accurate way. Professor Brouardel then very properly observed that the mortality statistics of tuberculosis were closely concerned in the declarations of the causes of death, and he emphasized the point that the reporting of cases of tuberculosis should be made strictly obligatory. Professor Landouzy brought forward the necessity for obtaining better mortality statistics, that is to say, of having statistics capable of furnishing a useful idea of the sanitary condition of the country, especially as regards tuberculosis. He urged upon the Académie the double necessity for the obligatory notification of tuberculosis and for compulsory disinfection of dwellings contaminated by the disease. He believed that among the defensive means at our disposal disinfection was the best, the easiest, and the least costly method of opposing the extension of the disease. Chauffard also thought that compulsory notification of deaths by tuberculosis was only a roundabout way of approaching the desired object, that of diminishing the death rate from tuberculosis. As the tuberculosis question was too urgent not to demand every effort, he proposed that the Académie should draw up a resolution to the effect that every death from tuberculosis should be followed up by a compulsory disinfection. Kelsch considered that it was visionary to looked upon disinfection as a heroic procedure, capable of restricting the spread of tuberculosis. The only measures, according to his view, which were useful were the suppression or the improvement of insanitary dwellings; by practising disinfection only, immediate contamination would no doubt be avoided, but the propagation of tuberculosis would not be very greatly diminished. Lereboullet asked that the Académie should not compel family physicians to report cases of pulmonary tuberculosis, and suggested that the notification be made optional; on the other hand, he attached much importance to the declaration of all deaths from tuberculosis, and laid stress on the necessity of supervising all the districts where the disease was active, and of carrying out disinfection of the dwellings and aiding in the treatment of the patients. Laveran also thought that compulsory notification of tuberculosis would be a useless and annoying measure. As a matter of fact, the experiment had been tried several years ago in certain quarters of Paris, where the municipal department of disinfection had carried out weekly fumigations. The patients were promptly looked upon as unclean, and it frequently happened that they were evicted from their dwellings. While Laveran expressed the wish that it might not be made obligatory to report cases of tuberculosis, he was strongly in favor of compulsory reporting of the death or change of residence of patients afflicted with the disease. It was very important to carry out disinfection of contaminated buildings. Professor Pinard expressed the same opinion, and said that he believed that compulsory reporting of all tuberculous patients would be impossible to carry out. In addition he considered that obligatory disinfection after every death from tuberculosis was impossible and would be insufficient. He thought that it was desirable not to force physicians to report cases of tuberculosis, but to give them the right of declaring disinfection necessary when they were convinced of its advisability. Besides, in order to make such a measure effective, it would be abso-

lutely necessary that it should receive complete support at the hands of the authorities.

The treatment of hydatid cysts of the liver was discussed at the Société de Chirurgie. Quénu said that the best method of treatment of these cysts, when their complete extirpation was impossible, consisted in incision, followed by extraction of the germinal membrane and simple suture of the sac. Before opening the cyst it was advisable to formalinize it in order to sterilize its contents, so that the peritoneum would be protected from danger through dissemination of the hydatid vesicles. This formalinization consisted in injecting into the cyst, after the fluid had been aspirated, from 200 to 300 grams of a 1 per cent. solution of formalin. Cysts of the liver treated in this way develop a serous exudation which is usually aseptic and which is absorbed after a longer or shorter period. Broca thought that the best method of treatment of these formations was incision, followed by suture, and said that he employed this technique except in the cases in which, after emptying the sac, he observed on examining its walls the existence of streaks of brown discoloration, indicating a transudation of bile through the superficial biliary bile ducts. Under such conditions he employed drainage. Ricard was able on the same patient to test the value of three methods of treatment of hydatid cysts of the liver. This woman had three cysts: one was extirpated, the second, which contained infected bile, was drained, while the third, with clear contents, was packed on account of severe hemorrhage from its walls.

At the Société de l'Internat the monthly address was held by M. Calmette, director of the Pasteur Institute of Lille, on the question of serpent venoms. After having reviewed the rôle of the serpent in legend and history, the speaker pointed out that among the modern races the Hindoos have retained the ancient veneration for this reptile. In India, death through serpent bites is extremely frequent, and the cobra alone claims 20,000 to 25,000 victims yearly. In France and in the other European countries the bite of the viper is not really dangerous except for children and feeble persons, but nevertheless there are about sixty deaths a year from this cause. In France there are two sorts of venomous serpents, the viper and the adder. Calmette then discussed the physiology of the venom. It is a digestive ferment, without odor or taste, that can be tested in solution in order to determine its toxicity. Animals into whom the venom of the adder has been injected manifest symptoms characterized by somnolence, paralysis of the muscles of the neck, vomiting, and finally paralysis of the respiratory organs, and death. The poison of the viper at first causes a local reaction, and the general symptoms do not appear until afterward. To produce antivenom serums, progressively increasing doses of different venoms are injected hypodermatically into a horse until it has been immunized. The serum of such a horse has marked curative power, and if injected within three hours of the bite it checks the poisoning and prevents death. It is a true specific against serpent bites.

Dr. de Wecker, who has died, was a noted ophthalmologist. Although born in Germany, he came to Paris early in life and practised there nearly forty-five years. He had written numerous important works, among which are: "A Treatise on Diseases of the Eyes," "Atlas of Diseases of the Eye Grounds," and more recently "A Treatise on Ophthalmology," which he published in collaboration with Landolt.

A cruise of French physicians is to be organized for the Lisbon Congress. Cruises to the banks of the Tagus have been planned by the English, the Germans, and the Americans, and it has therefore seemed fitting that the colors of France should also be represented. A steamer called *L'Etoile* has been chartered, and sailing from Marseilles it will proceed along the entire coast of Spain, giving the excursionists opportunities for visiting the places of interest and reaching Lisbon just in time for the International Congress.

The Treatment of Epistaxis.—Mendini recommends the introduction into the bleeding nasal passage of a tampon soaked with one part of a 1-1000 adrenalin solution and ten parts of salt solution; if this does not control the hemorrhage the passage must be packed with strips of gauze. In most cases this will be sufficient and it is rarely necessary to place a tampon in the posterior nares. In removing the tampons it is advisable, after the first few strips have been taken out, to drop into the nostril a small quantity of a solution composed of cocaine hydrochlorate one-fifth, 1-1000 adrenalin solution one, and distilled water ten. The vasoconstriction caused by this application produces enough shrinkage of the nasal mucosa to permit the tampon to be removed *in toto* without difficulty.—*Nouveaux Remèdes.*

Progress of Medical Science.

Boston Medical and Surgical Journal, March 29, 1906.

The Value of Drugs in Therapeutics.—F. C. Shattuck admits the uselessness of many of the old mineral and vegetable remedies, but finds value in many of the new synthetic compounds. Broadly stated, drugs are adjuncts only. What beneficial effects they have (outside of the few specific remedies) lie in their power to alleviate untoward symptoms. This is especially true in acute and chronic infections. In such diseases as cancer drugs may promote comfort and prolong life. In certain maladies more or less local, drugs may be indispensable while there are minor ills which a physician can modify by drugs, such as a purge in biliousness or autointoxication. Our general rules in drug giving should be (1) to do no harm; (2) to have a clear idea in our own mind whether we are giving a drug as a specific, a curative, a palliative or a placebo; (3) to give a drug uncombined as far as possible, though to this rule there are many exceptions. (4) When we are using an efficient drug, we should be as sure as possible that the preparation is efficient and then we should continue it till something happens, either the desired effect or some toxic manifestation. Disregard of this rule is, in the author's opinion, responsible for many therapeutic failures.

New York Medical Journal, March 24, 1906.

Some Eye Problems Which the General Practitioner Is Called Upon to Solve.—R. J. Tivnen advances the following propositions: (1) Ocular findings are of distinct diagnostic and prognostic value in systemic diseases. The clinical ocular manifestations observed in nephritis, diabetes, locomotor ataxia, syphilis, and rheumatism amply warrant this conclusion. (2) Foreign bodies in the cornea are frequently the source of serious disease of the eye. Infection may be introduced and ulcer, with its grave consequences, develop. Antiseptic measures, in their removal, are to be strictly observed. (3) Iritis, conjunctivitis, and sclerotitis may be confused in diagnosis. Care in distinguishing the distinct clinical manifestations of each will prevent the error. (4) Glaucoma may be diagnosticated as sick headache, persistent neuralgia, erysipelas, influenza, or toothache. In all such cases the tension of the eyeball is the correct guide. (5) The use of cocaine and atropine is not free from danger. Toxic symptoms may be produced. Contraindications for use of atropine are distinct, and tension should previously be estimated. (6) Squint in children should be treated early. The usual order of treatment followed is: A. Correction of refractive errors. B. Training of fusion sense. C. Surgical measures. Errors of refraction underlie the majority of cases and proper fitting of glasses may be all that is required.

The Diagnostic Significance of Colic.—G. P. La Roque mentions gastrointestinal disturbances, lead poisoning, tabes, gallstones, pancreatic lesions, renal calculi, and uterine, tubal, and ovarian abnormalities as causes of colic. He gives an elaborate differential table of symptoms as enabling us to distinguish between colic and peritonitis. Under each of the above headings the peculiar symptomatic characteristics of each variety are laid down. Nothing new is presented.

Perforating Ulcers of the Duodenum.—M. A. Austin gives a general description of the clinical features of this lesion, and adds the report of a personal case, appending a bibliography made up from cases reported in the *Annals of Surgery*. His own patient was a farmer of thirty-three years, who had been suddenly attacked with pain in the right side. The abdomen showed a diffuse tenderness, was not distended, but was rigid on both sides. The general condition was one of profound shock. In a few hours he had rallied somewhat, but before arrangements for operation could be completed he suddenly died. Autopsy showed the general peritoneum full of gas and fluid, nearly two gallons of yellowish, fresh-smelling fluid, such as would come from the stomach and duodenum, being evacuated. In the lower left quadrant of the abdomen was a well-marked obstruction of the small intestine, produced by a torsion, and the contiguous bowel appeared as if the obstruction had been present a number of hours. Following up the small intestine, fresh adhesions were found binding the cardiac end of the stomach and the duodenum to the liver and gall-bladder. On pulling the duodenum slightly, its adhesions to the gall-bladder separated and showed a typical ulcerative perforation of the duodenum about two inches below the pylorus, and

on the posterior surface and upper border of the duodenum was a perfectly clean punched out area of the gut wall. The serous surface showed a perforation 3-16 of an inch in diameter, and on the mucous surface there was an erosion 7-16 of an inch wide. There was no special induration around the ulcer and there were no signs of any accompanying ulcers in the stomach. There was no obstruction to the pylorus and no pathological changes in the gall-bladder or bile ducts. The author regards the case as one of acute ulceration.

An Explanation of Suggestions in Therapeutics.—This subject is discussed by B. F. Beebe, who regards the only rational explanation to be found in the physical basis and functions of the nervous system, and states that we must investigate the matter along the lines of physiological psychology. He says that since the vitochemical constitution of the millions of gray cells is the physical basis, and the sum total of their sense of feeling constitutes the emotion of the man, and that physical desire is the direct cause of impulse, it is not difficult to appreciate the direct connection between good and bad conduct and the normal and abnormal brain cells. "As we feel, we think, and as we think, we act," is an old truism. Emotional disturbances then are, in fact, the sum total of the physical or chemical commotions in the gray cells; and this commotio cerebri is great or little, according to the constitution of the cells and the influences affecting them. Thus every sensation of seeing, hearing, smelling, tasting, and touching becomes in fact a suggestion, and these act directly upon the brain cells, producing the so-called mental impressions. In this way, therefore, the whole world is swayed by psychic influence; that is, by suggestion. It is well to remember that no one does voluntarily other than he desires, and that the dominant desire is ever the will power for the time being. It is a great lesson that one should be careful how he constitutes his desires; how he constitutes the physical basis of mind, viz., his nervous system. Involuntarily and of necessity, says the author, do we respond to the dictates of physical desire. We should therefore be careful about forming our habits. Free will, he considers to be, in the strict sense of the term, nonsense. Determinism is the only rational conclusion. Our brains determine for us our every action.

American Medicine, March 31, 1906.

Prophylaxis of Lobar Pneumonia.—J. M. Anders believes that the prevalence of the disease is much influenced by indoor conditions, especially such as obtain during the cold season. Effective prophylaxis embraces four main objects: (a) The thorough disinfection of pneumonic sputum as well as that of healthy persons, including the secretions of the upper air-passages; (b) isolation of the patient, especially from the debilitated; and disinfection of the sick chamber, together with its contents, after death or recovery; (c) the removal of personal predisposition, and (d) the introduction of certain public measures. Thorough and prompt sterilization of pneumonic sputum and of the secretions from the upper respiratory tract and then the prompt destruction of the same by burning is a matter of first necessity. Disinfection of the bed-linen and body-linen, the mattress and the room occupied by the pneumonia patient is also a primary requisite. These matters do not receive the rigid care and attention which they richly merit by the average general practitioner. The public measures of greatest value may be summarized as follows: The issuance of drastic edicts against spitting on the sidewalks; the work of street cleaning and street sprinkling should be looked after by bureaus or boards of public health, to whom should be given full executive authority; there should be greater diffusion of popular information concerning efficient ventilation of our office buildings, theaters, courts of justice, manufacturing establishments, churches, public schools, and passenger and street railway cars, and also regarding details connected with the subject of the prevention of lobar pneumonia stating simple, plain facts about the way in which the disease is spreading.

Cystitis.—Charles C. Norris reports two cases which are typical of two of the rarer forms of the disease. In Case I, a vesical calculi formed around a heavy silk suture. Two years previous the patient had had a suprapubic cystotomy performed for severe cystitis. This gave temporary relief. A few weeks later the patient passed a silk ligature covered with urinary salts. Following this, or for the last two years, the patient had symptoms of cystitis and occasional interruption of the stream of urine. Cystoscopic examination revealed a stone about the size of a pigeon's egg suspended from the superior aspect of the bladder. Vaginal cystotomy and removal of the stone was done. The wound healed rapidly and the patient was discharged cured four weeks after operation. Case II was one of exfoliative cystitis, the patient being a colored woman of thirty-two, with no evidence of gonorrhea. Acute cystitis occurred with sudden onset. Symptoms for the first week were very severe. Three weeks later the urethra became blocked by a sloughing mass, which on removal proved to be an entire cast of the bladder, consisting of the mucosa and a portion of the muscularis. Symptoms from this time began to subside, and two months later the patient was entirely well. This case had no assignable cause. The uterus was in normal position, there were no neoplasms blocking the pelvis, nor was the patient pregnant. No strong chemical solution had been used in the bladder.

The Conradi-Drigalski Medium for the Isolation of B. Typhosus.—Clarence L. Cole, in studying this subject, divided the work into the following four steps: (1) Transferring colonies from plate cultures prepared the preceding day to litmus milk, glucose agar, bouillon, potato, and ordinary agar. (2) Examination of cultures in the different mediums. (3) Preparation of plates for inoculation. (4) Inoculation of the plates. The results of the investigation are given in tabular form, which serves to show the number of cases from which *B. typhosus* was isolated, as well as the appearance of cultures in litmus milk, the motility and the reproduction of organisms isolated from the stools and which produced blue colonies upon lactose litmus agar. The medium served only to differentiate the colonies of *B. typhosus* from acid producers, but in that way facilitated the identification of that organism. Success with the medium in obtaining *B. typhosus* from every case depends in a great measure upon repeated examinations, and the difficulties encountered formerly in work of this character are only removed in the proportion which the colonies of *B. typhosus* present bear to those of acid-producing organisms.

The Pathology of Rabies.—A. Gordon gives a detailed account of the pathological findings in a case of rabies. He points out the constancy of Van Gehuchten's and Nélis' characteristic findings in the spinal ganglions. He calls attention to the absence of Négri's bodies in his case, bodies which are also considered by some writers as pathognomonic of the affection. Babes' tubercle is not a constant finding in rabies. Finally, he draws special attention to the presence of mast-cells, which, as is well known, were found in inflammatory areas. Since these cells were found by Dr. Gordon in the spinal ganglions, in which the characteristic lesion of rabies is usually found, he concludes that the presence of mast-cells corroborates the view that the ganglions are the place of predilection for rabic virus.

Journal of the American Medical Association, March 31, 1906.

Acute Dilatation of the Stomach.—J. B. Herrick reports two cases of acute gastric dilatation, one of which terminated in recovery, the first case, he thinks, with such outcome when complicated by pleurisy or pneumonia. Herrick reviews the symptoms, the distention, the characteristic vomiting, etc., and remarks on the diagnosis and the extremely unfavorable prognosis in these cases. The value of the succussion sound in diagnosis is emphasized. He is convinced that the treatment used in this successful case was life saving. It consisted in frequent gastric lavage, use of normal salt solution hypodermically and by the rectum, nutrient enemas, and hypodermic use of strychnine and digitalin. He also used a binder in his case, which he thinks possibly helped somewhat, at least, by keeping the stomach in its proper place. The possible value of ice applications in causing the stomach to contract is also mentioned. Herrick thinks it a treatment worth trying in future cases, though he did not employ it. Hot water or even hot air introduced into the stomach through a tube, he thinks, might also be of value. The etiology is in many cases obscure and the theories of the disease are not entirely satisfactory.

Intracranial Hemorrhage.—R. P. Peairs reports three cases of head injury illustrating his argument of the importance of early operative interference in certain conditions. In all three cases there was a head injury, followed by coma and pressure and irritation phenomena, but no definite localizing symptoms. In all three there was extensive meningeal hemorrhage over the right hemisphere. One of the patients, treated expect-

antly, waiting for the appearance of focal symptoms, died; the other two, operated on without waiting for such symptoms, recovered. He calls attention to these facts and to their bearings in the treatment of similar cases. The absence of focal symptoms does not mean that hemorrhage is not present, and valuable time may be lost in waiting for their appearance. He believes that an operation is indicated when there is a history of head injury, followed by loss of consciousness, if the patient has a persistent slow pulse, that is, one of fifty or under, later becoming rapid, and is gradually growing worse. It is certainly less dangerous to operate than to treat the case expectantly. No doubt many of these patients will die under any treatment, but he believes that many more could be saved by prompt surgical means.

The Neurons.—L. F. Barker reviews the history of the neuron doctrine and the actual state of our knowledge of the subject at the present day. He comes to the conclusion that "none of the theories opposing the neuron conception has led to the objective demonstration of the existence of a real continuity among the nerve elements," and that there is a marked difference between so-called neuronists and anti-neuronists in the interpretation of the known facts. The former admit only what is demonstrable, and not finding intracellular anastomoses, they do not feel called on to admit that they exist. The latter, while equally unable to demonstrate their existence, hold that they ought to exist, that continuity is *a priori* so probable that those who deny it should be compelled to prove to their satisfaction that it is impossible. He suggests that the multiplication of hypotheses may have been largely due to the assumption that the neurofibrils represent the sole conducting element in the nervous system, a point by no means yet satisfactorily proved. The questions of the possibility of nerve conduction, apart from the cell body and of the autoregeneration of nerve, are noticed, and the known facts discussed. Barker does not venture a positive opinion on either of these points, but does not deny their possibility. The disputed question as to the unicellular or pluricellular origin of the neuron and its peripheral nerve fibers is taken up and the remarkable investigations of Dr. Ross Granville Harrison, demonstrating that motor nerve fibers develop as processes of the anterior horns instead of being developed from the neurilemma cells along their course, are mentioned as among the most important of the recent contributions to our knowledge of the subject. But even if the pluricellular origin of the neuron could be demonstrated, it would still be an anatomic unit, but as an organ rather than a single cell.

The Blood-Clot Dressing.—H. O. Reik believes that the blood-clot dressing, recommended by Blake of Boston, in the mastoid operation, best meets the needs and offers the best results. Those who have tried it report no unpleasant results, and he thinks that it more nearly restores the natural conditions than do other methods in use. Even if the wound is not absolutely clean the normal blood possesses certain bactericidal power, which is greater after it is drawn from the vessels than while still in the circulation. It is present only when the blood is alkaline, and he thinks that some of the failures of the blood-clot dressing are perhaps attributable to the use of chemical antiseptics in cleansing the wound. On theoretical grounds, it would seem more rational to rely on dry cleansing with instruments and sterile sponges, or by washing out the wound with sterile salt solution, which, if it has any effect on the clot, would increase its alkalinity and power to control septic action. He adds some words on the technique of the blood-clot dressing: First, absolute cleanliness and removal of every particle of infected material; second, the closure of the wound in such a way as to prevent the introduction of new infection and to promote primary union. Chemical sterilization should be avoided and sterile salt solution should be used if irrigation is deemed necessary. Finally, for the closing of the wound the subcutaneous silver wire suture recommended by Halsted may be used. It can easily be disinfected and is itself antiseptic, and can be removed without pain at the proper time. A silver foil covering over the closed wound will add something to the protection. Reik believes that this will come to be accepted as a standard method in mastoidectomy.

The Treatment of Appendictis.—C H. Wallace, St. Joseph, Mo., divides appendicitis into six stages: (1) Inceptive stage, first forty-eight hours; (2) rapidly progressing stage, third, fourth, and fifth days; (3) nonprogressing or stationary stage; (4) interval, or chronic stage; (5) abscess stage; (6) the diffuse peritonitis stage. In the first of these all surgeons and many internists agree as to the advisability of operation. In the second, few surgeons favor operation, and observation shows that it increases rather than lessens mortality. Here Ochsner's plan of lavage and peristaltic rest by rectal feeding is sound surgery. In the third, rest and a guarded diet is advised, the case should be allowed to pass on to the interval period. This, the fourth stage, is the time for hopeful and ideal surgery. In the fifth, or abscess stage, he prefers two safe operations rather than one dangerous operation, first opening the abscess and later removing the appendix. In the sixth stage he believes that the least manipulation means the least mortality; simple incision with effective drainage with Fowler's position is the most hopeful treatment. Wallace summarizes his views as follows: "I believe, with the mind open for conviction and liable to complete reversal by future advancement, that: First, appendicitis is always a surgical disease. Second, every patient should have and is entitled to operative measures within the first forty-eight hours. Third, the rapidly progressing stage is the stage of applicability of the Ochsner treatment, and this offers the lowest mortality. Fourth, in cases coming to the surgeon with evidence of gradually subsiding symptoms, operation should be deferred to a more favorable period. Fifth, operation should be urged in every interval or chronic stage. Sixth, in abscess cases, two safe rather than one hazardous operation should be done. Seventh, in diffuse peritonitis all dependent cavities should be carefully incised and drained and not flushed, and, secondarily, the offending organ should be removed."

The Lancet, March 17, 1906.

Local Anesthesia for Cosmetic Operations.—L. E. Stamm commends the use of eucaine combined with adrenalin, the former of the strength of 4 per cent. and the latter of 1 per cent. Injections are made in the usual way around the lines of the intended incisions, care being taken to inject in the course of the nerves supplying the area. Fully fifteen minutes should be allowed for the anesthetic to take effect.

Multiform Streptococcic Infections Apparently All Derived from the Same Source.—Four cases are reported by A. Latham, E. P. Paton and H. D. Bruë. Case I was one of facial erysipelas in a girl, convalescent in ten days. Case II was that of the girl's mother, who had a swollen and painful right shoulder and later an inflamed area of skin and subjacent tissue, affecting the right chest and running down to the hip. A general septic condition resulted which proved fatal on the twelfth day. Case III was a sister of Case II, who had cared for the latter, and on the day after the latter's death complained of pain and tenderness in the right axilla. An abscess eventually formed in this locality and pus was evacuated, containing streptococci in pure culture; recovery. Case IV was the father of Case I, admitted to hospital with a sore throat and tonsils covered with yellow patches. General sepsis developed and streptococci were found in the blood. Death resulted in five days. In this series of cases one form of streptococcus appears to have been the cause throughout, but the nature of the illness produced varied in each case. This shows, say the authors, that though the form of the invading micrococcus may be the same in two cases, it by no means follows that the type of infection or its virulence will be of the same nature as the source from which the infection was derived. Ordinary erysipelas is well known to be due to a streptococcus. In the above series of cases a streptococcus would no doubt have been found in the erysipelas case if it had been looked for. It is particularly interesting, however, to note that the other cases, which there can be little doubt were infected from the case of erysipelas, did not develop this disease, but in one case a virulent form of cellulitis, without suppuration, accompanied by general septicemia, in a second case a local infection with suppuration, and in the third case an acute septicemia with suppuration in the peritoneum, primary infection being apparently in the tonsils. There is, of course, another reasonable explanation of the source of infection in these cases—namely, that they were all due to defective sanitation in the house in which the patients lived.

Splenomegalic Polycythemia.—One case is reported by R. Hutchinson and C. H. Miller, the patient being a man of forty-five years with an enlarged spleen, eight million red cells per c.mm. and one hundred and ten per cent. hemoglobin (Haldane). The general progress of the case after admission to the hospital was one of

gradual failure of the vital powers, with progressive stupidity, complete somnolence, and death. Full autopsy findings are given in the original paper. Increased viscosity was found to exist in the blood, and the general complex of symptoms strongly resembled those of previously reported cases, to which Weber has suggested the name of myelogenic polycythemia. Referring to individual symptoms as explained by autopsy findings, the authors note that the loss of vision and along with it attacks of giddiness and the terminal stupor, could be explained by the extensive areas of thrombotic softening found in the occipital lobes of the brain. That the amount of blood-forming tissue in the bone marrow was increased, cannot be doubted. This, with the absence of any signs of increased blood destruction in the liver, would point to the polycythemia being the result of an increased formation of red cells. The enhanced viscosity of the blood, which is the consequence of the polycythemia, and the abnormal strain which it throws upon the arterioles, may perhaps explain the high degree of vascular fibrosis met with. The fibrotic degeneration of the heart was certainly a most striking feature of the morbid anatomy, but was perhaps merely secondary to the thickening of the walls of the coronaries. As regards the softening in the occipital lobes of the brain and the large, pulpy areas in the spleen, there can be no doubt that they were due to thrombotic necrosis, the consequence of stagnation of blood which the high viscosity of the latter tended to induce. No evidence was found of any primary tuberculosis of the spleen such as has been alleged to occur in some of these cases, and the authors are inclined to think that in such descriptions, areas of infarction may have been mistaken for tuberculous foci.

British Medical Journal, March 17, 1906.

Painless Labor.—A case is reported by J. Allan of a young primipara who complained of slight pains in the stomach and upper abdomen. Examination revealed a slightly dilated os, full term having been reached and everything progressing in a normal manner. The child was born unconsciously, the mother experiencing no pain whatever. Recovery was uninterrupted. The perineum was not injured. Within two hours the os had dilated from a size of admitting only two fingers to a size allowing the safe passage of an eight-pound child.

An Aid to Prognosis in Typhoid Fever.—According to R. M. Simon, polyuria is a sign of good omen in typhoid fever. He submits a summary of 214 cases. Of these, 21 died. In 18 of these, the amount of urine was low, never exceeding 40 oz. Of the remainder, in 138 cases there was marked polyuria. In the other 55 cases no polyuria was noted, though in all of them the amount exceeded 40 oz. before convalescence was established. Of the 138 cases in which polyuria occurred, 16 showed a large amount throughout; in 28 polyuria began after the fall of temperature; in 34 it occurred before the fall of temperature; and in the remainder it showed itself as the temperature fell to normal.

The Transmissibility of Syphilis to Apes.—A note on this subject is made by A. S. Grünbaum and R. D. Smedley. A male chimpanzee was inoculated on the eyebrow by rubbing into it a portion of a chancre freshly excised. Signs of infection, indicated by some duskiness of the skin and a small nodule, appeared on the sixteenth day. For some days later these signs seemed to regress, but then general swelling and induration of the eyebrow with duskiness of skin became very evident. More recently exfoliation of the skin, leaving a surface yielding a serous or sero-purulent secretion, has occurred. The cervical glands on the same side are enlarged. The general health of the animal seems unaffected, and there is no rise of temperature. Although sought for, the *Spirocheta pallida* was not found until the thirty-seventh day after inoculation.

Physiological Notes on the Cancer Problems.—Sir W. Wade believes that, theoretically at least, the damage which leads to cancer may be due to something taken away from tissues rather than to something added, not necessarily in the cells, but perhaps in something behind the cells. He suggests that the growth of the cells up to a state of ripeness is due to the action of the motor nerves. This theory he applies to the mammary gland during lactation. The question now arises, what is the relation of the motor nerves during periods of long quiescence? *e.g.* between lactations and after the menopause? Is it possible that the nerve has also some inhibitory influence, and that while it does not drive the cells in one direction it prevents them from developing in another, prevents them, for example, from exercising that inherent and intrinsic power of growth the possession of which seems to be indicated by their mode of origin. If this is so, abolition of the nerve (for example, its withering) at the menopause might leave the cells at liberty to exercise this faculty of growth, unless it also was abolished at the same time. What results such an unfettered mode of growth would give we have not the least idea. But it might lead to the formation of gametoid cells or of cells which could not resist the entrance of leucocytes. Such symbiosis resulting in the formation of a new entity, with new endowments, something after the fashion of the formation of a lichen from the combination of a fungus with an alga. The development of cancer in the female reproductive organs at the menopause enforces still more powerfully in the author's mind the idea that the disease has its prime origin in some structural or vital default, either in the cells or in the nerves dominating them. He submits the suggestion that the origin of cancer may be intimately connected with senile changes in the nerve endings or in the cells or perhaps with both these combined.

Berliner klinische Wochenschrift, March 12, 1906.

The Virulence of Tubercle Bacilli.—Marmorek points out the difficulties attending a comparison of the degrees of virulence of different strains of tubercle bacilli. If the ordinary laboratory animals, such as rabbits or guinea pigs, are used, their susceptibility to the infection renders it almost impossible to recognize any differences in intensity. Marmorek employed the mouse, which is refractory to tuberculous infection under ordinary conditions, after having rendered the animal more susceptible to the bacillus. This he effected by injecting together with the emulsion of bacilli from 0.15-0.20 of a 2 per cent. solution of hydrochlorate of quinine. This substance paralyzes the power of phagocytosis and therefore reduces the resistance of the animal. By this method Marmorek was able to determine that two or three days old cultures of tubercle bacilli are much more virulent than those of the same strain which are several months old. If very small doses of young bacilli are injected intraabdominally into the mice the animals show lesions in the lungs after twenty or thirty days; if the same amount of old bacilli plus quinine is injected even after six or eight weeks no lesion is visible and it is only after the expiration of five or six months that the first tubercles can be demonstrated. The virulence of tubercle bacilli therefore depends on the age of the culture and decreases with long growth.

Inguinal Hernia of the Uterus.—Hilgenreiner describes a case of inguinal hernia in which the uterus formed part of the contents of the hernial sac. The organ was so firmly adherent that it was impossible to effect its complete liberation and consequently it was made use of in a plastic operation to assist in closing the very large hernial opening. He also reproduces in brief the histories of fifteen other cases of the same condition which he has collected from the literature, and which added to those collected by Birnbaum and Brunner, bring the total number of reported instances up to thirty-nine. The patients were women of all ages, though the condition seems to be most common in those of middle age who have passed through several pregnancies. In about half the cases the hernia was congenital, and in about half the cases also congenital malformations of the genital organs were noted. The prognosis of operative treatment is good.

Münchener medizinische Wochenschrift, March 13, 1906.

A Very Delicate Reaction for Bile Pigments.—Krokiewicz recommends the following reaction: Reagent A consists of a 1 per cent. watery solution of sulphanilic acid; reagent B is a 1 per cent. watery solution of sodium nitrite, and reagent C is pure, concentrated hydrochloric acid. The first two reagents should be kept protected from light. In order to make the test 1 c.c. each of A and B is well shaken in a test tube and most of the mixture is poured out so that about one-half c.c. remains behind. About the same amount of the urine or other fluid to be tested is added and well shaken. If bile is present the fluid becomes ruby red, the color changing to amethyst violet on the addition of one or two drops of hydrochloric acid and dilution with two or three volumes of distilled water. In fluids containing large amounts of bile it is better to dilute strongly with water before applying the test. The reaction indicates the presence only of bilirubin or slightly oxidized bile

pigment and is never produced in the urine after the internal administration of any of the drugs that are apt to interfere with the ordinary tests for bile. The author also states that it is more sensitive than the tests in ordinary use.

The Diagnosis of Extrauterine Pregnancy by Means of the X-rays.—Lichtenstein, who believes that the presence of fluid in the tissues is one of the greatest obstacles to successful radiography, describes a case in which the diagnosis of extrauterine pregnancy was made before operation by means of an *x*-ray photograph. In discussing this case he points out that it is easier to secure a successful radiograph of an extrauterine fetus than of one contained within the uterus. In extrauterine pregnancy the fetal membranes are thinner and contain but little if any liquor amnii. If the pregnancy is advanced the fetus usually emerges from the tube and finds a resting place in the surrounding parts so that the placenta comes to lie at one side; in the uterus, however, the placenta commonly overlies the fetus and offers an additional barrier to the penetration of the rays. In other words the greater amount of fluid which is present in the tissues and surrounding parts in the normal pregnancy accounts for the difficulty that is experienced in securing successful radiographs in this condition. That even a comparatively slight difference in the amount of fluid contained in the tissues may be of considerable importance as regards the success of the radiograph is shown by the fact that if two radiographs are made of a still-born child, the one immediately after birth and the other after the body has been preserved from twelve to fifteen days, the skeleton will be much more clearly marked on the second plate, owing to the dehydration of the tissues that has been effected by the preserving fluid.

The Treatment of Acute and Chronic Suppurations with Phenolcamphor.—Ehrlich says that while Bier's principle of treatment by hyperemia has met with universal commendation on the part of all authors, the method is difficult of application under the conditions of ordinary practice on account of the necessity of constant supervision of the patients by trained attendants which it entails. Ehrlich, in making preliminary observations on the action of the phenolcamphor mixture recommended a short time ago by Chlumsky, was so impressed with the value of the combination that he undertook an extensive series of tests in a garrison hospital, where, owing to the fact that the patients are always of the same class, satisfactory comparisons between the different methods of treatment could be made. He has treated by the phenolcamphor combination ninety six cases of all sorts of suppurative conditions. The result has been very gratifying, and as fifty of the patients were treated in the military hospital the conclusion that the time of treatment was considerably shorter when phenolcamphor was used than under the older methods of wet dressings and extensive incisions, can be verified by the official statistics. The mixture is composed of thirty grams of carbolic acid, sixty grams of camphor, and ten grams of alcohol. The oily fluid which results is employed as a wet dressing on gauze, or ganze saturated with it is packed lightly into suppurating wounds. The applications produce no undesirable effects, and in addition to their curative action are markedly anodyne.

Deutsche medizinische Wochenschrift, March 15, 1906.

Protective Inoculation in Man with Living Plague Bacilli.—Kolle and Strong describe a method of securing immunity against plague infection by means of protective inoculation with pest bacilli that have been reduced in virulence by repeated transplantations on artificial media. After experiments on animals had shown the nonpathogenicity of an organism that had been treated in this way a condemned criminal was inoculated with it. As no bad results followed, experiments were made on other persons with larger amounts and forty-two individuals have now received inoculations of an entire agar culture. A slight local reaction lasting two or three days is produced, as well as moderate fever extending over the same period, but the discomfort is said to be no greater than that attending ordinary vaccination. Animal experiments prove the high degree of immunity conferred in this way and the serum of the persons treated not only presented specific agglutinating properties for fresh virulent plague bacilli but also manifested well-marked protective power when injected into animals. The authors consider that it may be regarded as an established fact that the injection of such plague bacilli cultures is harmless, but they warn against attempts at application of the method unless the nonvirulence of the particular culture to be used has been demonstrated. Strains of plague bacilli which do not kill guinea pigs when given in the dose of two agar cultures may be regarded as harmless. Inasmuch as the living organism is used in producing immunity in this way the authors consider that it may be regarded as a true type of vaccination in the Jennerian sense.

The Use of Oil Enemata for Chronic Constipation in Infants.—Wunsch speaks highly of the use of injections of olive oil as a means of securing a cure in cases of obstinate constipation in nursing infants. The causes of the condition are numerous, but frequently in spite of all possible attention to the mother's diet, the hygiene of the infant's anus, etc., and the application of the customary remedies including ordinary enemata, suppositories, abdominal massage, laxative drugs, etc., attempts to cure the difficulty are ineffectual. In these cases the use of an enema of olive oil repeated about other day for a certain length of time may bring about a normal activity of the bowels. In illustration the author describes a case which had baffled all other means of treatment but remained permanently cured after eight injections of olive oil.

Meningococcus Pharyngitis as the Underlying Cause of Epidemic Cerebrospinal Meningitis.—Ostermann describes culture experiments made on the families of the patients in six cases of cerebrospinal meningitis in an attempt to discover how many of those coming in contact with patients carry meningococci on their nasopharyngeal mucous membranes. Out of twenty-four persons examined seventeen were discovered to be cocci carriers, the identity of the meningococcus in each case being established by cultural methods and by agglutination with a specific serum. The author points out that this demonstration of the fact that a very large proportion of the apparently healthy persons in the environment of patients are the hosts of virulent meningococci, renders the problem of prophylaxis an extremely complicated one. Suitable tests showed that the organisms could be transmitted through the medium of the fingers, eating utensils, handkerchiefs, in coughing and in talking, etc. On the other hand, no measure has as yet been devised for checking the growth of the organisms in these persons, as their site of predilection is in the nasopharynx where they appear to be thoroughly protected against all ordinary therapeutic applications. Prophylaxis must therefore consist largely in warning the people in times of epidemics of the disease to avoid as much as possible coming in contact with others or being present in crowded places of public assembly. Regulations regarding the safe disposal of expectoration and nasal mucus should also be promulgated, and people should be warned to keep at a distance of about three feet in speaking or coughing.

French and Italian Journals.

A Case of Rapid Malignant Syphilis Complicated by Alcoholism.—J. Schwetz points out the particularly unfavorable effect which alcoholism has upon the human organism when there is also present another chronic morbid condition. The aggravation of the effects of syphilis by the presence of alcoholism is becoming more and more evident. The writer refers to recent researches in relation to general paralysis which tend to prove that this affection is the result of the combined influence of syphilitic virus and alcoholic poison. He then gives the history of an alcoholic, a woman forty-nine years old, who contracted syphilis. Specific treatment was instituted, but the patient could not resist her desire for alcohol. Her symptoms became more and more alarming, and within eight months after first being seen by the writer she succumbed. This patient's husband, who was similarly afflicted with syphilis, but whose habits were good, was apparently cured by appropriate treatment.—*Revue Médicale de la Suisse Romande*, February 20, 1906.

Pregnancy with Dermoid Cyst of the Two Ovaries. Epitheliomatous Degeneration of One of the Cysts. Double Ovariotomy.—M. G. Chavannaz declares that cancerous degeneration of dermoid cysts is of three types: Epithelial, sarcomatous, and endothelial. The co-existence of two dermoid cysts, one of them undergoing cancerous degeneration, with pregnancy, is exceptional. The writer then gives a detailed history of a patient presenting these complications. The patient was thirty-seven years old and had had four children. In the present pregnancy at about four months the symptoms indicated operation. A cystic tumor of the ovary or of the tube, with perhaps a slight torsion of the pedicle, was diagnosed. Laparotomy discovered on the right of the uterus a tumor the size of an orange. There were many adhesions. The tube, red and very large, was situated in front of the tumor. The

pedicle of the latter was twisted. Both tumor and tube were extirpated *en masse* without puncture. The left ovary was the size of a large nut, and was removed, together with the tube on this side. On the anterior parietal peritoneum of the right side, three hard, small vegetations were also extirpated. The operation was not followed by any unhappy results. The patient, however, succumbed to a recurrence of the malignant growth. Histological examination of the epithelioma.—*Journal de Médecine de Bordeaux*, February 25, 1906.

Extraction of a Fibrous Uterine Polypus Immediately After Labor.—Janvier relates the history of a case which he has recently observed. He was called to attend a woman who was in the first throes of labor. Within the last sixteen years she had had two children, nine years apart. It was about mid-year in 1903 that the patient began to suffer from menorrhagia, but she did not consult a physician for this trouble. On February 18, 1905, the flow ceased with the beginning of pregnancy. The patient had daily violent colic. A tumor was detected, which was situated in the lower part of the abdomen. Pregnancy was terminated by a natural delivery, but the uterus remained large. The contractions became more and more violent and the writer, thinking of the possibility of a twin pregnancy, introduced his hand into the uterus. He discovered implanted on the fundus a mass larger than the head of a fetus, and he diagnosed a fibrous polypus of the uterine cavity. As the patient was becoming weak from the considerable loss of blood, Janvier decided upon intervention. The tumor was pedunculated and was removed by torsion. It weighed 520 grams. The hemorrhage was arrested at once and the patient began to improve. One month later she was out of bed.—*Revue Française de Médecine et de Chirurgie*. February 25, 1906.

The Cutaneous Eruptions of Malaria.—M. Claude says that, like the majority of intoxications and of diseases in general, malaria has its cutaneous manifestations. Billet was one of the first to describe these lesions and his observations of febrile malarial erythema are all supported by blood analyses. The origin, then, of these lesions is undeniable. Moty has reported certain observations of cutaneous gangrene which were observed during malarial infection. He believes that this was caused by the obstruction of the capillaries by melaniferous leucocytes, consequent failure of nutrition, and final necrosis or gangrene of the tissues. Whatever may be the cutaneous lesions noted, very often febrile, in a malarial country, they ought always to suggest the possibility of malaria. The writer appends the history of a number of cases in point. He concludes that every cutaneous manifestation occurring in a malarial patient seems to augur a relapse more or less grave. In order to prevent a serious relapse, all appropriate therapeutic measures ought to be taken, in spite of the fact that experience seems to show that they have little effect.—*Le Caducée*, March 3, 1906.

Experiments on the Pathogenesis of Round Ulcer of the Stomach.—G. Zironi has attempted to produce round ulcer of the stomach in animals by resection of the vagus below the diaphragm, and gives us his conclusions. In rabbits this procedure produced gastric ulcer in one half the cases operated on. It is impossible to say whether these ulcers would rapidly cicatrize, thus showing that they were of a different nature from true gastric ulcer, which shows no tendency to healing. The ulcers produced were in the pyloric portion of the stomach. Fourteen animals were operated on, and most of them were killed after eleven to seventeen days. In one not killed until the sixtieth day there was a cicatricial nodule found, such as would have remained after a healed ulcer. The ulcers were the size of a pin-head, mostly round, sometimes double, and situated in the greater curvature, or at the pyloric end.—*La Riforma Medica*, February 10, 1906.

Infantile Cerebral Paralysis, Post-Scarlatinal.—Salvatore Pastore discusses the origin of cerebral paralysis as a result of infective diseases, especially scarlatina. The cerebrum and other parts of the nervous system may be affected by various microorganisms, such as *Bacillus coli*, typhoid bacillus, staphylococcus, pneumococcus, diphtheria bacillus, erysipelas germ, and scarlatinous poison. The effects on the nervous system are produced by the toxins generated, and not directly by the germs. The forms of myelitis that are produced by germs are anterior poliomyelitis, acute ascending spinal paralysis, and acute spinal paralysis. These infections are epidemic. Cerebral lesions of various kinds may also be produced. The author presents a case of spastic paralysis resulting from scarlatinal infection, which began about the thirtieth day of the disease, in a child of six years. At first there was complete hemiplegia, with facial paralysis and aphasia. The upper extremity remained permanently paralyzed, with contracture, athetoid movements, and normal electrical reaction. We may distinguish the case from anterior poliomyelitis by the fact that the leg recovered and the arm remained paralyzed, by the contracture, the exaggerated reflexes, athetosis, and normal reactions. The history contradicted the belief that it might have been a monoplagia. Had it been a spinal paralysis it would not give a history of hemiplegia, as that is the common form.—*Giornale Internazionale delle Scienze Mediche*, February 15, 1906.

Constricted Liver Lobes and their Surgical Treatment.—Guido Senni states that constriction of a portion of the liver occurs in women, never in men, the lobe becoming atrophied and displaced downward. It is referable to tight lacing. The location varies with the level at which the constriction occurred, as well as the amount of tissue involved. The constriction may become pedunculated. The predisposing cause is ptosis or hypertrophy of the organ. It is never found in children or men. The cystic duct follows the descent of the liver and stasis of the bile occurs, resulting in calculus. Diagnosis is made by finding a tumor in the right side of the abdomen, connected with the liver, moving with respiration; dullness is continuous with that of the liver; the hepatic flexure of the colon is pushed down with the tumor so as to lie obliquely across the abdomen. Pressure causes atrophy of the liver tissues, and the peduncle slowly forms by which it is held to the liver, containing blood-vessels and bile ducts. There may be no symptoms observed by the patient, or the tumor may be felt by her, or there may be disturbances of digestion and of the nervous system, and pain, with sensation of dragging in the abdomen. There may be resonance from the colon heard behind the tumor, and the percussion area of the liver is changed. Treatment by abdominal bandages is useful in some cases. In most cases an operation must be performed to relieve symptoms. Fixation to the abdominal wall has been done with success, and the constricted portion may be removed.—*Il Policlinico*, February, 1906.

Lumbar Puncture in Cerebrospinal Hemorrhages.—Marc Hérault has made a very careful study of this subject. He states that if the liquid is white the central origin of the hemorrhage can be recognized by complex methods only. Histological examination is necessary in such cases. If the liquid is red, especially a yellow red, and if it gives the spectroscopic and chemical reactions of hemoglobin and if there has been no error in the technique it can be quite safely affirmed that the hemorrhage is of central origin. If the liquid is yellow its color may be of hematic origin, of biliary origin, or of sero-chromic origin. Lumbar puncture which results in the collection of a bloody liquid containing red globules proves the existence of intrameningeal hemorrhage. A yellowish liquid is an almost sure index of hemorrhage in the state of resorption. As to the diagnostic value of hemorrhagic cerebrospinal liquid, as far as the etiology of the hemorrhage is concerned, it is relative and must depend upon the history of the case, clinical appearances, and the study of the other characteristics—cytological or microbiological—of the cerebrospinal liquid. Every cranial or spinal traumatism, whether or not it be followed by fracture or dislocation, may or may not yield a hemorrhagic, bloody liquid on lumbar puncture. By successive punctures the evolution of a hemorrhage—its resorption and infection—may be followed. As well as in surgical hemorrhages, lumbar puncture is of value in medical hemorrhages. By this proceeding has been recognized the existence of meningeal hemorrhages in the course of cerebrospinal meningitis, of septic meningitis (pneumococcus), of fibrous meningitis, and of tuberculous meningitis.—*Revue Française de Médecine et de Chirurgie*, January 25, 1906.

Achondroplasia.—Auché has recently had a patient with this affection under his care. The child is about three years old. The mother is twenty-six years old and in good health. The father died by accident at the age of thirty-two, but was in good condition. This child was born at term, but at birth the enormous size of the head and the small size of the body was very noticeable. He walked at eleven months and cut his first tooth when nine months of age. Last year he underwent an operation for inguinal hernia. His body is small while his head is as large as that of an adult. The teeth are a little carious, but have a normal implantation. The arms as well as the legs are short. The musculature is very well developed. The genital organs and all of the visceral organs are normal. The patient will be subjected to thyroid treatment.—*Journal de Médecine de Bordeaux*, January 28, 1906.

Book Reviews.

A Text-Book on Psychiatry for Physicians and Students. By Leonardo Bianchi, M.D., Professor of Clinical Psychiatry and Neuropathology in the Royal University of Naples; Minister of Public Instruction in Italy; Medical Director of the Provincial Asylum of Naples; Corresponding Member of the Medico-Psychological Association of Great Britain and Ireland, etc. Authorized Translation from the Italian, by James H. Macdonald, M.B., Ch.B., Glasg., Senior Assistant Physician to the Govan District Asylum. With 100 Illustrations. New York: William Wood & Company, 1906.

In these latter days when, more than at any other period in the world's history, of the making of books there is no end, a new work, whether on general medicine or dealing with some special branch, must be distinguished by some feature peculiar to itself if it would win the favor of the reading medical public. Of books on psychiatry there is no dearth, and many of them are seemingly so complete as to leave no room for another treatise, at least until this science has progressed far beyond the point at present attained. Most of these, however, approach the subject from the side of symptomatology and treatment—a very practical side, indeed, yet not entirely satisfying to the student of mental aberration who is not content with a simple classification and a ticketing of the multitudinous deviations from the mental norm, but would know the pathological basis of the conditions that confront him. This is perhaps the distinguishing marks of Bianchi's treatise, that it strives to unveil the pathogenesis of psychic disease by a close study of the physiology and pathology of cerebral function. The author has endeavored to correlate the results of all who have been working independently in the various fields of biology, psychology, physiological and pathological chemistry, cerebral anatomy and histology, bacteriology, and other lines of investigation bearing directly or indirectly upon the normal and abnormal workings of the human mind. This is not to say that other recent writers on psychiatry have altogether neglected these foundations of the science, but they have not delved therein to the extent that Bianchi has delved. This is perhaps natural, since it is in the Latin countries, especially Italy and Spain, that the most signal advances have been made in cerebral and neural physiopathology. The treatise before us is not, however, so purely "scientific" as not to be practical. The all-important subjects of symptomatology and treatment are not ignored, but are treated of in a thoroughly comprehensive and practical manner.

The work is divided into three parts, following the usual introduction. In the first part the author treats of the normal anatomy and physiology of the brain—of its centers and paths. Part II. is devoted to a consideration of the physiopathology of perception, attention, memory, ideation, the emotions and sentiments and the will, and of consciousness. This is the introduction to the clinical section, in which is considered the symptomatology of mental disease—"to the examination of the symptoms of the disordered mind, and to the analysis of their signification in relation to the facts of normal psychology and to the laws which govern their manifestation." In the final and largest section, the author enters upon the clinical side of his subject, treating of the different diseases of the mind, their symptoms, and their treatment. This section is illustrated with many case histories. The classification which the author has adopted will be found to differ in some respects from those usually followed. In some cases he has grouped together diseases which other writers regard as distinct, in others he has separated certain clinical forms which are usually classed—"confused," Bianchi says—under one name. Many psychiatrists will not agree with the Italian author in this rearrangement of mental disorders, nor will they follow him in his conception of the physiopathological basis of some of the psychic disturbances, but they will find food for reflection in what is here contained, and for specialists this is after all what is sought for in a treatise. For students of this branch of medicine Bianchi's work will be found an excellent foundation, and whatever in it may be contra-orthodox may be corrected by the teachings of other authorities, of whom there is fortunately no lack.

A Laboratory Manual of Physiological Chemistry. By Elbert W. Rockwood, M.D., Ph.D., Professor of Chemistry and Toxicology and Head of the Department of Chemistry in the University of Iowa, etc. Second Edition, Revised and Enlarged. With One Colored Plate and Three Plates of Microscopic Preparations. Philadelphia: F. A. Davis Company, 1906.

In the second edition of this manual, which appears now after a period of seven years has elapsed since the first was issued, the author brings the subject-matter thoroughly up to date in accordance with the many advances of physiological chemistry. The book comprises not only a series of laboratory lessons, but also covers in outline the theory of the subject and should suffice for the needs of the elementary student, in conjunction with the oral teaching of the laboratory and the lecture room. No attempt is made to cover the more abstruse phrases of the subject, and the elementary facts and principles of physiological chemistry are lucidly brought out. The book in this second edition will prove acceptable to students as well as to teachers.

Pharmacology and Therapeutics. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Attending Physician to the Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital; ex-President of the American Therapeutic Society; Fellow of the American Academy of Medicine; Vice-Chairman of the Revision Committee of the United States Pharmacopeia, etc. Sixth Edition; based on the Fifth Edition of White and Wilcox's "Materia Medica and Therapeutics." Philadelphia: P. Blakiston's Son & Co., 1905.

This is the larger and concluding volume of the author's work on Materia Medica and Therapeutics, the former volume of which was noticed in the Medical Record of February 10. In these two volumes there is, of course, much repetition; at the same time they are essentially different, particularly in the classification employed. In the former volume the classification was based on the class and chemical division or natural order to which the therapeutic agents belong; in the present volume the basis of classification is the particular physiological system upon which the drugs and other agents chiefly act. There is a very complete list of drugs and preparations, with dosage, and a detailed account of their physiological action and therapeutics. The two volumes cover the ground of Materia Medica and Therapeutics very thoroughly; indeed, the work is almost encyclopedic in its completeness. We would recommend the first volume more particularly to the medical student, and the present one to the practitioner.

Differential Diagnosis and Treatment of Disease, a Text-Book for Practitioners and Advanced Students. By Augustus Caillé, M.D., Fellow of the New York Academy of Medicine; Member and ex-President of the American Pediatric Society; Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Visiting Physician to the New York Post-Graduate and German Hospitals; Consulting Physician to Isabella Home and Hospital. With 228 Illustrations in the Text. New York and London: D. Appleton and Company, 1906.

The plan of this book differs from that of most medical treatises in that it deals only with the purely practical aspects of disease, the etiology being merely alluded to in brief paragraphs and the pathological anatomy being practically ignored. Diagnosis and treatment, prophylactic and curative, are the subjects dealt with, and dealt with most thoroughly, by the author. The book is not adapted for the use of students, since it omits a consideration of the fundamentals of the study of disease, but for the practitioner, who is supposed to be grounded in the fundamentals and needs for immediate application reminders on the practical points of diagnosis and treatment, we know of no more generally satisfactory work. We wish the author were a little more hopeful in his therapeutics and had not confined himself quite so rigidly to a consideration of the measures which he personally regards as efficacious. In the treatment of disease there is a wide latitude of opinion, and the writer of a text-book should not ignore methods of treatment which other authorities have found serviceable, even though he cannot endorse them himself. A lecturer before a class of students or post-graduates naturally and properly expounds his own views, but the writer of a text-book cannot, or should not, ignore the work of other therapeutists. The reader expects to find a résumé of all that is known on the subject, even if certain methods are mentioned only to be condemned. For this reason we cannot recommend this work as all-sufficient for the young practitioner, but this is not to say that we do not recommend it at all. On the contrary, it is a book that should be in every physician's library, for the part dealing with diagnosis is superlatively good, and that treating of therapeutics bears the stamp of originality and individuality which is most valuable, only—it must be supplemented with other works written by men with other views of treatment. The reviewer, it is needless to say, is a therapeutic optimist, and he does not like to see methods which he has found, or thinks he has found, useful, entirely ignored in a work put forth as an authoritative guide in the treatment of disease. He may be an enthusiast, but in the vital subject of the saving of life he would have the floating oars charted as well as the life-boats and rafts. With this reservation, Dr. Caillé's book can be commended as a thoroughly practical and useful guide to the young practitioner.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held March 1, 1906.

THE VICE-PRESIDENT, DR. W. GILMAN THOMPSON, IN THE CHAIR.

Resolutions Relative to the Smoke Nuisance.—A resolution was offered and passed that a public hearing be given by the Department of Health, in order that those who have complained of the smoke nuisance might be heard; and also that what had been received by the Council concerning the abatement of it be referred to the Board of Health, with the recommendation that the Health Department renew the agitation for a stricter enforcement of the law governing the smoke nuisance.

The scientific business of the evening was devoted to a consideration of the upper air tract as affected by influenza, and was held under the auspices of the Section on Laryngology and Rhinology.

Lantern Slides of Sections of the Nose and Accessory Sinuses.—Dr. LEWIS A. COFFIN gave this lantern slide demonstration.

Etiology and Bacteriology of Influenza.—Dr. WILLIAM H. PARK presented this paper, which was read by Dr. Field. He described influenza as we understood it at present, and said that in years following a pandemic the cases became less characteristic and more difficult to separate from other infections. At first it would seem an easy matter to find a bacillus now known to be so abundant in the bronchial secretions, but in view of the fact that it required hemoglobin, or some derivative of it, for growth, it was easy to account for the failure. Therefore on the usual culture media it did not grow, while the pneumococci and streptococci in the throat did grow, and thus led to confusion. The influenza bacilli were, as a rule, in great numbers in the characteristic tenacious, yellowish-green expectoration of those suffering from influenza. The first sputum coughed in the morning was apt to be the best for bacteriological examination. If a little of this was smeared on a cover glass and stained with weak carbolfuchsin, 1 part in 10 solution, there would be seen, if the case were one of true influenza, great numbers of tiny bacilli arranged in characteristic groups or lying in or between the pus cells. The smears were stained for five minutes. The cases in which the nostrils, rather than the bronchi, were attacked, were less easy to study by smear examinations, as many other bacteria were apt to confuse the picture. The background of the field appeared a pale red, from which stood out the red nuclei of cells and the bright, tiny bunches of influenza bacilli. Other bacteria, when present, were usually less deeply stained. The influenza bacilli were decolorized by Gram's method. No spores were ever developed. Although the smear examination gave a probable identification, it was not absolute; only a pure culture made identification possible. There was still a difference of opinion among bacteriologists as to whether certain bacilli were those of influenza or not. Rabbit, pigeon, sheep, horse, and human blood were used to furnish the hemoglobin necessary for the development of the bacilli. The influenza group comprised both the influenza and the pseudoinfluenza bacilli. The latter contained the Koch-Weeks bacillus, the pseudoinfluenza bacillus, the *Bacillus catarrhalis*, the bacillus of whooping-cough, the trachoma bacillus, and others. At present there were but few cases of characteristic pure influenza, but this bacillus or some closely allied form was still frequently met with as associated with other bacteria. For instance, for about one month last winter there was a very fatal form of bronchopneumonia following laryngeal diphtheria. In nearly every case cultures from autopsies showed nearly half, or more than half, the bacteria in the lung to be influenza bacilli. In measles, scarlet fever, whooping-cough, bronchitis, and other inflammations of the respiratory tract, this part was at certain seasons frequently the seat of infection with the influenza bacillus. At other times few were found. Tuberculous cavities in the lung were especially the seat of influenza bacilli. In times of pandemics the majority of cases considered to be influenza clinically, prove so bacteriologically. Several years after an epidemic, when the cases became milder, it was practically impossible to say whether most cases of so-called grip were due to influenza bacilli or to the pneumococcus or other organisms. The autopsies in fatal influenza cases often showed many tiny cavities containing pus. Many severe cases that recovered suggested the same conditions, as the patients coughed up large amounts of sputum containing purulent masses. These cases might persist for months and years with influenza bacilli. A large percentage of advanced consumptives were found to be infected with the influenza bacilli. Influenza bacilli from cultures or in sputum when dried rarely lived forty-eight hours. It seems impossible that they ever lived over one or at most two weeks. It was impossible to produce influenza in animals except in the higher monkeys. There was a moderate immunity which lasted for some months after a true infection with the influenza bacillus. Prophylaxis seemed almost impossible; the expectoration, however, should be carefully attended to so as not to reach others in any way. The intervals between the great epidemics were too long to attribute them wholly to the lack of suitable persons for infection.

Symptoms and Treatment of Influenza.—Dr. CLARENCE C. RICE read this paper. He said that while influenza manifested itself by many points of attack and by most varied clinical phenomena, we ought not in our zeal for difficult diagnosis to attribute simple catarrhal processes to the special infection which alone could produce influenza. He reviewed the history of this affection from the fourteenth century. In discussing the clinical phenomena he called attention to the three or four days of mental and physical depression which often preceded the nasal and pharyngeal outbreak as being peculiarly significant of influenza, although this incubation was not nearly as apt to be present when the disease was epidemic and virulent. The symptoms were those of a severe nasal and pharyngeal catarrh, and within twenty-four hours the infection usually reached the pharynx. There was no characteristic regularity of temperature in the nose and throat cases of influenza. The temperature was apt to be remittent in character, after the first outbreak of fever, which ran from 101° to 104° F. The nasal passages were more or less occluded by soft tissue swelling. The congestion was observed by Dr. Jonathan Wright to be more bluish in tone than in acute coryza. In influenza there was no regularity in the amount or kind of secretion. The rhinitis did not, from the standpoint of discharge, run the course of a simple coryza. The matter of relapse was an important differential point. The most experienced physician could not state positively when the catarrhal symptoms were at an end, for even if there was no lasting lesion the infection might perhaps attack a sinus, the post-nasal space, or the ear, and again there might be symptoms of general depression and muscular weakness, so that recovery was slow and discouraging. If such secondary inflammation had not taken place by the end of the third or fourth day, danger of such complication was usually over, though these complications had followed after the patient was up and about. An attempt to classify the rhinitis of influenza into the catarrhal, the hemorrhagic, and the purulent stages was not very correct clinically, but was useful for purposes of description. In regard to the hemorrhagic variety, it was undoubtedly true that epistaxis was more apt to occur in an influenza than in simple rhinitis. It was also true that bleeding occurred frequently in cases where there was a preexisting ulceration of the cartilaginous septum, but the hemorrhagic variety could hardly be

called a distinct type. Blood might be found present in ordinarily severe cases where there was not more than the usual degree of nasal congestion, or it might be found where there was a hemorrhagic diathesis. The hemorrhagic rhinitis commenced with the same catarrhal symptoms as did the more common variety, and the bloody discharge did not usually appear until the third or fourth day, although in virulent cases the blood might appear at the onset of the disease. The blood came as frequently from the middle turbinated region, where there were no ulcerations, as from the preexisting erosions on the nasal septum. The diagnostic value of the ecchymotic spots which were occasionally seen on the soft palate and uvula was considered by Franke as very great in doubtful or chronic cases. Dr. Rice had also noted such localized areas of congestion, and one should bear in mind their importance in differential diagnosis. Permanency of congestion of the anterior pillar could be explained by the strong tendency to chronic congestion of the tonsils, this long-continued hyperemia of the tonsils leaking through into the anterior pillars. Submucous hemorrhagic infiltration in the larynx had been observed, and a hemorrhage into one vocal band was not an uncommon occurrence. In speaking of purulent discharges, it might be said that some degree of admixture of pus might be present at any time, even if there was no special symptom of sinusitis. When the discharge remained almost entirely purulent there was strong probability that the sinuses were involved in the acute process. Purulent inflammation of the sinuses occurred much oftener in the course of influenza than in a simple catarrh, and was much more apt to become chronic, because the nasal tissues remained congested and thickened for so long a time and drainage was so greatly interfered with. All writers were agreed that sinus disease was much more frequently a complication of grip than of any other form of rhinitis. In the minority of cases grip attacked the pharynx before it did the nasal passages, and developed some grade of tonsillar inflammation and general catarrhal pharyngitis before it ascended to the post-nasal cavity and nose. What had been said of nasal swelling was true also of the pharynx. The congestion was greater in simple catarrhal tonsillitis, but in influenza it was firmer, lasted longer, and recovery to normal size took longer. Swallowing was not so painful as in acute follicular tonsillitis. Exceptionally influenza attacked the larynx first and later extended downward into the bronchi. In these rare cases the nasal and pharyngeal symptoms were slight in nearly all cases. Cough, hoarseness, and partial loss of the voice were prominent symptoms, though the congestion and swelling were not very pronounced. The recovery of the voice was characteristically slow. Among extraordinary manifestations of influenza might be classed the hemorrhagic type, sinus disease, and that condition graphically described as septic edema of the upper air passages. Deviations from the normal in the nasal passages did not predispose to influenza, as was supposed by many, but enlarged tonsils might furnish vulnerable foci for infection. No specific therapeutical agent was known whereby influenza could be quickly aborted or controlled. The indications for treatment were to support the strength, to control the fever and the pain, and by judicious care to prevent such complications as chronic catarrh of the nose and pharynx, suppuration of the sinuses, middle-ear disease, dangerous inflammation of the larynx and bronchi, and to ward off pneumonia. Disastrous results could be avoided by resting in bed longer than was usual, and remaining in a warm and even temperature. Since there was no great general prostration, cathartics should be sparingly used. Sedatives were indispensable in controlling pains in the head and body. Ice packs applied to the forehead, nose, eyes, neck, and throat during the early stages were useful. Bloodletting in the nose and tonsils had served a useful purpose in plethoric subjects. He did not recommend sprays of cocaine and adrenalin. A sedative and protective powder, like the compound stearate of zinc, to which less than one-half of one per cent. of cocaine had been added, with perhaps a small amount of menthol and camphor, was preferable. Nasal washes should be alkaline and used by means of a douche cup. He did not think well of the spray for the anterior nares.

Dr. Henry L. Swain of New Haven, Conn., opened the discussion. He said that when changes in the upper air tract showed themselves in influenza, two distinct pictures occurred to him, which he contrasted. It had been shown that the germ of influenza was with us, and might remain in the system for two years, in the cavities of the lungs, for instance. Therefore it might be stated that the germ did not exist there without, under certain conditions, producing some effect. The contrast pictures were made from the experience of a rhinologist and otologist. At a European clinic some time ago a bleb upon the drum was shown as the rarest of clinical experiences. At New Haven he saw twelve such cases, and every year seemed to bring its quota of vesicles upon the drum. Again, abroad he saw two rare cases of acute pharyngeal sinusitis; yet in his comparatively small practice in New Haven he saw sixteen similar cases. Every year he saw cases of grip in a modified course, and the range of symptomatology must now be shown to have altered. Among the possible causes for this he mentioned the depression caused by the germ, the use of the coal-tar derivatives, and the tremendous speed in which we lived. In grip the germs gained access to the system in a different manner than other germs did; the integrity of the epithelium was broken, which permitted the entrance of the germs. The prevention of grip depended upon cell integrity. It was the ciliated epithelium cells which were the easiest affected by the grip germ; if this was denuded, then the grip germs may gain an entrance and give rise to the active manifestations of the disease.

Dr. C. G. Coakley said that the reports made upon smears from the nasal cavity in cases of influenza gave a mixed infection; seldom, if ever, was a pure culture obtained. Since 1890 many cases of chronic sinusitis had been attributed to influenza, and he thought this was wrong. To-day we were better able to diagnose these cases than we were in 1890; the methods of diagnosis were to-day almost perfect, and, therefore, more cases were diagnosed to-day than formerly, thus making it appear as though there were more cases. Pain was a symptom that often was ascribed to neuralgia; yet it might be found in many cases that the accessory sinuses were occluded, producing an obstructive headache, and not a neuralgia. So far as treatment was concerned, it should consist in establishing drainage when the accessory sinuses were involved. Anything which would open up the nose and contract the mucous membrane, and allowed the secretions in these cavities to get down and out, would be efficacious. Solutions of adrenalin, if judiciously used, were of value. Laryngeal hemorrhage was partly due to the condition of intense enlargement of the blood-vessels and the spasmodic cough which accompanied the disease; it was, in fact, a traumatic hemorrhage.

Dr. James E. Newcomb continued the discussion, speaking of the relation of influenza to the trachea. In looking up the subject he found that there were twenty or more cases recorded in which the particular symptom had been hemorrhage from the tracheal walls, and in more than one-half of these there had been given histories of a previous attack of grip; in practically all of these there was a history of more than one attack. Most of the patients were young adults. The sexes suffered alike. The youngest patient was sixteen years old. He thought such attacks of tracheal hemorrhage were more numerous than the published reports led us to believe. Every physician had had cases of hemoptysis without apparent cause; tuberculosis

had been suspected but did not develop, and the patients had been dismissed and the source of the hemorrhage remained a mystery. If such cases were followed a sufficient length of time, they might be enabled to make a classification of them. There was in each case a history of influenza. In such cases the most prominent symptom was the tickling and cough, some elevation of temperature if influenza was present, but none otherwise. The chest would show nothing in particular, and no bacilli would be found in the expectoration. The peculiar thing about it was that on examination of the upper trachea with the laryngeal mirror there would be found a varicose condition of the tracheal vessels. Blood in some cases had been seen to trickle down the clean tracheal wall. Dr. Newcomb believed the best treatment to be rest in bed, opiates, and spraying of the upper part of the trachea; astringent sprays could be used without ill effects. The important thing to consider in these cases was whether or not these were manifestations of tuberculosis, or did they belong to a class by themselves. Were these cases of incipient tuberculosis, with one expression of hyperemia? Many of these cases had been followed, but tuberculosis had not developed. This region was very vascular and it bore the brunt of the impact when the patient coughed. If there was an impaired local vitality, bearing in mind the fact that this was one region in which the influenza bacilli primarily attacked individuals, it was not at all uncommon, or impossible to believe that the influenza bacilli were responsible for the development of the varicose condition of the tracheal veins.

Dr. Emil Mayer said a question of much import was whether one was dealing with an ordinary catarrhal condition or with influenza, and too much stress could not be laid upon this. When one considered the greater amount of temperature which appeared as a rule in influenza, when one considered the wonderful amount of depression, when one considered that many members of the same family had a similar complaint, all seemed to him to be sufficient for the diagnosis of influenza, made without the necessity for expert knowledge. He agreed with Dr. Rice that cases of accessory sinus disease were more often associated with influenza than any other form of rhinitis. A great deal of discomfort was caused by this congestion of the nasal mucous membrane closing the nose, but he never used cocaine in such cases because of its dangers, and because it gave only a temporary relief. Adrenalin was his sheet anchor, if properly used; adrenalin in strengths from 1-5,000 or 1-10,000 should be used, with a small amount of sodium chloride added, which contributed greatly to the patient's comfort. Irrigations in some acute cases was of great value. Although it seemed impossible to drain the antrum of Highmore properly, yet by washing out this antrum great comfort was afforded these patients.

Dr. Robert C. Myles said that he had made a study in the anatomical rooms, for eight or ten years, of the nose and accessory sinuses, and he learned as much during the last year as during the first. After referring to the possible methods of prevention by isolation, disinfection, etc., he said that in the treatment of these cases he advocated the use of vapors of various antiseptics. Inspiring medicated air was beneficial. In the chronic cases one had a tremendous amount of work to do in the accessory sinuses, the disease conditions being kept up because of the lack of proper drainage. In cases in which the trachea and bronchi were involved the best results were obtained by tracheal injections, the medicament being dropped between the vocal cords, not introducing any instrument into the trachea. His favorite drug in such cases was iodoform.

A Modern Mummy.—The body of M. Markoff, the great Siberian railway contractor, says the St. *James's Gazette*, has been stuffed by his widow, fitted with glass eyes, and garbed in dress clothes, and it now inhabits a richly inlaid cabinet in a corner of Mme. Markoff's drawing room.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, March 2, 1906.

The President, Dr. T. Mitchell Prudden, in the Chair.

A Case for Diagnosis.—Dr. W. Gilman Thompson showed a man, forty-two years old, formerly a sailor and now a painter and paperhanger, who until two years ago had enjoyed good health. He then began to suffer from slight gastric distress after eating. Subsequently to this, he noticed that he became short of breath and blue in the face upon even slight exertion, or with any change of posture, such as stooping or lying down. There was evidently some obstruction to the circulation in the head and neck. On lying down his face became intensely congested, and dyspnea developed. Raising his arms above his head produced the same symptoms. A beginning aneurysm was suspected, but no other symptoms of it, other than the above, could be made out. Physical examination was absolutely negative, and the *x*-ray showed nothing.

Dr. Edward G. Janeway said there was evidently some pressure on the veins of the neck, and while an aneurysm was the most likely assumption, its presence could not be proven at this time. Future developments would have to be awaited. He drew attention to the paradoxical arterial pulse and venous flow.

Dr. Beverley Robinson said that aneurysmal tumors at times gave rise to very queer symptoms, particularly when associated with abnormalities of the heart or large vessels. The postural symptoms in this case might be due to congestion of the veins, or possibly to pressure on the larynx, which was a very sensitive organ. He suggested an examination of the larynx.

A Case for Diagnosis.—Presented by Dr. W. Gilman Thompson. The patient was a man, thirty-four years old, a motorman, who had a large mass in the left hypochondrium which had given rise to no symptoms whatsoever excepting a certain amount of gastric pain, coming on about one hour after taking food. There had never been any vomiting. The tumor had existed about nine months; it was a mass four or five inches in diameter, very hard and somewhat nodular, and the exact nature of it seemed doubtful. There had been some loss of weight, but with a carcinoma of that size more rapid emaciation would be expected. There was no history of injury. There was marked enlargement of the iliac glands on both sides. The possibility of Hodgkins' disease beginning in the abdominal glands had been considered, and also of pancreatic disease. There was no secondary anemia; no syphilitic or alcoholic history; the blood and urine were normal.

Dr. Janeway suggested inflation of the stomach and of the colon, in order to see the relation of the growth with these organs.

Dr. Robert Abbe thought the growth had more of a cystic than a solid feel, and he suggested that the case was possibly one of cyst of the tail of the pancreas, with some little induration of its surface. In reply to the question as to whether he would advise an exploratory operation in a case of this kind, he said that he saw no objections to an exploratory operation.

Dr. Walter B. James said he had never seen a case of Hodgkins' disease in which such an extensive glandular development in the abdomen was not accompanied by some enlargement of the glands in the neck. The case rather impressed him as being one of tumor of the tail of the pancreas, or possibly an irregular enlargement of a displaced spleen. As to whether an exploratory operation should be undertaken, that would depend, he thought, on whether the patient was growing worse or not.

Some Points of Discussion Relating to the Prevention and treatment of Pneumonia.—By Dr. Beverley Robinson. (See page 529.)

Dr. James said he was so enthusiastic in regard to the value of fresh and clean air in pneumonia that he would

hesitate to dilute it even with creosote. He had tried creosote some years ago—not as thoroughly or persistently, however, as had Dr. Robinson—and his results, both by the inhalation and internal use of the drug, were no better than they were in cases where it was omitted.

Dr. Edward G. Janeway said he felt about as Dr. James did in regard to the value of fresh air in pneumonia, and he generally aimed to have the patient kept in an airy, well-ventilated room. In some cases creosote seemed to do good, but it was difficult to say how much good. It was not so very long ago that blood-letting was regarded as the only rational method of treating pneumonia, and the same was practically true of the tartar emetic treatment. There was a time when no one thought of using strychnine in pneumonia; now the patients were not expected to get well without it. Dr. Janeway said he liked to divide his pneumonia cases into two classes: Those that required medicine, and those that in all human probability would get well without it. He could recall cases where one entire lung was involved, which recovered without medicine; the temperature did not demand it, the heart did not demand it, the lung did not demand it, and, above all, the patient and his family did not demand it. Again, he had seen cases of pneumonia recover under various methods of treatment; one physician pinned his faith to morphine, another to whiskey, another to digitalis, and a fourth, perhaps, to strychnine. Some physicians believed in withholding cardiac stimulants until the heart appeared actually to demand them, while another class seemed to think it advisable to spur on the heart from the very beginning. In speaking of the value of carbonate of creosote in pneumonia, Dr. Janeway said he had seen cases in which it was given early with unsatisfactory results. At times, he thought that oxygen inhalations were undoubtedly of value, and he recalled cases in which there was marked cyanosis of the lips and fingers, and the patients were seemingly *in extremis*, which were apparently successfully tided over by the use of oxygen. Rather free cardiac stimulation was also beneficial at times, and for that purpose he favored digitalis in some form, or a combination of strychnine, digitalis, and nitroglycerin. The hypodermic use of camphor oil might occasionally cause abscesses, yet was much used. The solution in sterilized sweet almond oil was better than in olive oil, because of its running more readily through the needle. As the remarks were not intended for publication, the subject was not fully developed, nor the question of alcoholic stimulation carefully considered.

Dr. W. Gilman Thompson said he wished to emphasize the value of a leucocyte count in pneumonia, to which Dr. Robinson had referred, and the importance of having it done by an expert. Otherwise, especially in cases in which cyanosis was marked, the result might be very misleading. In regard to the value of creosote in pneumonia, given either internally or by inhalation, Dr. Thompson said that a very thorough trial of the drug, extending over a period of a number of years, had convinced him that it was utterly worthless. Furthermore, he was convinced that the treatment of pneumonia by any method of inhalation was without value and had no physiological or pathological basis. The late Dr. J. West Roosevelt, in a paper read before this Society some years ago, had emphasized the fact, already known, that the depth to which a substance could penetrate the lung by inhalation was very limited. The physiology of respiration showed that only one-tenth of the air of the lungs was mechanically exchanged in each act of respiration, the rest of the process being due to the diffusion of gases. In pneumonia, the respiration was very shallow, much more so than in health, and the involved lung was absolutely solid, so far as the penetration of air was concerned. It was utterly irrational to conclude that any inhalation could reach the deep-seated portions of the affected lung, or modify the growth or development of the bacteria or their toxins. The pneumococcus was a fairly hardy microorganism, and it was not justifiable to presume that its destruction would be accomplished by inhalations of creosote or chloroform. In catarrhal conditions of the upper air passages, the inhalation of certain medicinal substances was no doubt beneficial, but their effect probably did not extend below the trachea, or larger bronchi. The fresh-air treatment of pneumonia, which had recently achieved considerable newspaper notoriety, was a very old one. In his own experience with this method of treatment at Bellevue Hospital, the results had been beneficial. After being kept out of doors for a number of hours during the day, it was found that the patients slept better, and the course of the disease seemed to be favorably affected. He had recently collected a series of cases of pneumonia in which recovery took place without any medical treatment whatsoever, the essentials of the treatment having been fresh air, rest in bed, and good nursing. Pneumonia patients were very easily exhausted, and one of the most important factors in the treatment was that they should receive a sufficient amount of rest. For that reason all meddlesome interference or over-solicitude by friends or nurses and the too frequent disturbance of the patient for the purpose of giving hypodermic injections, or food, or inhalations, should not be permitted. This, of course, did not refer to the administration of the necessary drugs and nourishment. In the very severe type of cases, in which the toxic symptoms were marked, saline irrigations or infusions were indicated. The speaker said he had seen a number of such cases, practically moribund, where a resort to these measures strengthened the circulation and produced a certain degree of improvement, tiding the patient over to the crisis, which was not far distant.

Dr. Lewis A. Conner said he had had no experience with inhalations of creosote in pneumonia, but about three or four years ago, when creosote carbonate was being advocated for that disease, experiments were begun with it at the Hudson Street Hospital, and these had been continued up to the present time. Every second pneumonia patient treated in that institution during the past three or four years had been given carbonate of creosote in addition to the routine treatment. Some 500 or more cases had been treated during this time, and while the results of the two series had not yet been compared statistically, he felt justified in making the general statement that there was no appreciable difference in the behavior of those treated with the creosote and those in whom it had been omitted. It did not give rise to any disagreeable symptoms nor disturb the stomach, but, on the other hand, it was apparently of no benefit. Alcohol, in any form, was now rarely given in pneumonia at the Hudson Street Hospital, and apparently its withdrawal had proven beneficial to the patients.

Dr. Andrew H. Smith said that while we were constantly hearing about the presence of the pneumococci in the mouth and upper air passages, there was very little said about their presence in the smaller bronchial tubes. Some years ago, with the idea of investigating this subject, he had quite a number of observations made in the dead-house on subjects who had died of other causes than pneumonia, and in those cases it was of frequent occurrence to find the pneumococci in the secretions of even the smallest bronchi into which a loop could be introduced. This proved that the microorganism was not confined to the mouth and upper air passages, but its behavior on those mucous surfaces was very different from that which it assumed on a serous surface. On the former it was comparatively innocuous, and it might even be disseminated throughout the bronchial tree without doing any harm, but when once it invaded the infundibula and air cells, and reached the pavement epithelium of those organs, we were apt to hear from it.

In reply to Dr. Thompson's objections to the value of inhalations, Dr. Smith said that if we accepted them it would be difficult to account for the well-known action of

anesthetics. The vapor of chloroform and ether certainly found its way pretty well down into the lung structure and into the system, and the blood that was charged with those drugs reached the air cells, even if they could not get through the bronchial tubes. It was through the medium of the blood that the results of inhalation were obtained. The speaker said that from his experience he believed that certain drugs, such as the carbonate of creosote and sodium salicylate had a decided effect on the pneumonic process, and that as the result of their administration the defervescense, instead of being by crisis, as it ordinarily was, usually took place by lysis. These substances seemed to possess some property which changed one of the essential phenomena of pneumonia, and reversed the ratio usually observed. They should not, of course, be used to the exclusion of other remedies. Dr. Smith said he did not agree with Dr. Thompson that the pneumococcus was a fairly hardy microorganism. It was probably the most vulnerable coccus with which we were familiar. Besides, its actual destruction was not necessary, and there was the widest difference in the world between *inhibiting* the action of a microorganism and *killing* it. In his opinion, the assumption that the pneumococcus reached the air cell by way of the lymphatics instead of through the air passages was gratuitous.

Dr. T. Mitchell Prudden said that inferences as to the presence of the pneumococcus in the deeper recesses of the lungs, which were based upon their alleged presence at autopsies, should, he thought, be accepted with considerable reserve. The researches of Norris and Pappenheimer, recently made under the auspices of the Pneumonia Commission of the Health Department, had shown that after death the exudates from the mouth and upper air passages, together with the bacteria which they contain, might find their way into the deeper portions of the lungs. It should further be remembered, he thought, that many of the earlier supposed identifications of the pneumococcus were not to be considered as altogether positive, in the light of the more recent and more subtle technique through which the absolute identification of this organism must be made. Finally, it was always to be remembered, in framing hypotheses based upon the presence of bacteria in the lungs, that in these organs the mechanism for the destruction of bacteria was under normal conditions extremely effective.

Dr. Prudden thought the practitioner might wisely hold in mind that pneumonia, like all other infectious diseases, was a process of adaptation of the body on the one hand, and of the microorganism on the other, to a new environment. Successful adaptation of the body to the microbe and its poisons in pneumonia, whether it be marked by crisis or not, was the result of a series of extremely complex and subtle processes which should not at least be interfered with by the treatment of the physician, and for which, so far as we knew, there was no substitute. The physician could apparently be useful in just so far as he was able to keep the body in such a condition that it could effect its own cure, but cure must be effected in the body's way, and by the body's mechanism, and not in any other fashion.

Dr. Thompson, in reply to Dr. Smith, said it was not at all necessary, for the purpose of producing anesthesia, to have the ether or chloroform penetrate deeply into the lung. The same effect had been produced by introducing ether into the rectum. Ether was an exceedingly diffusible vapor, much more so than creosote, and the same was true of chloroform. The point he wished to emphasize was that when the lung was solid with a pneumonic exudate, it was scarcely rational to believe that the germs that were producing that exudate could be reached by inhalation.

Dr. Beverley Robinson, in closing, said he did not believe that creosote, by inhalation, penetrated consolidated lung tissue, but he did claim that the inhalation of the drug in pneumonia had a beneficial effect on the course of the disease. His faith in the efficacy of the drug was based upon clinical experience. While he was not in a position to refute the statements made by Dr. Thompson in regard to the penetrability of certain drugs by inhalation, he could not accept as final the results of the experiments made by the late Dr. Roosevelt.

College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting held January 8, Dr. George Dock read a paper entitled "Clinical Observations on Exophthalmic Goiter (Graves' Disease), with Special Reference to Complete and Incomplete Forms, the Clinical Course and the Treatment." The paper dealt at length with the various phases of the question, and was based on an experience with thirty-two cases. Dr. James Tyson read a paper on "The Medical Treatment of Exophthalmic Goiter." Rest, with freedom from excitement was a most important therapeutic measure. Bromides were often useful. Strophanthus would aid in the control of the rapid heart-action; an ice-bag applied over the precordium was a useful adjunct for the same purpose. Thyroid extract was an uncertain remedy for exophthalmic goiter. Thymus extract had been used by some clinicians with success. Adrenalin should be a physiological antidote. Dr. W. G. McCallum of Baltimore presented a communication entitled "The Pathogenesis of Exophthalmic Goiter." In a study of the tissue obtained by removal of the enlarged thyroid gland in a considerable number of cases of exophthalmia he had found anatomical conditions indicative of compensatory hypertrophy. The colloid was diminished; the vascular supply was rich. The walls of the veins were friable and the connective tissue contained a good deal of lymphoid tissue having a nodular arrangement. Dr. Joseph C. Bloodgood read a paper entitled "The Surgical Treatment of Exophthalmic Goiter." The operation consumed much time and was likely to be attended with considerable shock. Therefore local anesthesia was to be preferred. Only a part of the enlarged gland was to be removed. Death might occur during or in succession upon the operation. The immediate relief afforded was most striking. Sometimes, however, the symptoms returned and the gland became again enlarged, so that secondary operation might be required.

Philadelphia County Medical Society.

At a stated meeting held February 15 Dr. Joseph Walsh read a paper entitled "Prognosis in Tuberculosis." He pointed out that a judgment as to the course and outcome in a case of pulmonary tuberculosis must be based upon the size, character, and number of the lesions, individual peculiarities, temperature, appetite, food, environment, social position, and a variety of other factors. Dr. Charles Lester Leonard presented a communication entitled "The Treatment of Some Superficial Benign Lesions with the Roentgen Ray." Among the affections thus successfully treated have been lupus, acne, glandular enlargements, simple goiter, exophthalmic goiter. Drs. George E. Pfahler and M. C. Thrush read a paper entitled "A Case of Exophthalmic Goiter Apparently Cured by the *X*-rays." The patient was a young woman presenting enlargement of the thyroid gland, exophthalmos and tachycardia, and amelioration of all of the symptoms ensued upon systematic application of the *x*-rays. Dr. W. Reynolds Wilson read a paper entitled "The Use of Calomel in the Treatment of Eclampsia." He pointed out the depurative, cholagogue, and antiseptic effect of calomel and its influence in the elimination of the toxic substances upon whose activity the eclamptic state is thought to be due. When the attack is threatening doses of ten grains may be administered, but when the attack has begun even larger amounts may be employed.

Surgical Suggestions.

After-Treatment in Hemorrhoid Operations.—Sir Victor Horsley in this connection says that the most important consideration is adequate provision to protect the line of suture against the passage of the feces, and at the same time to save the patient from the intolerable pain caused by the old-fashioned plan of "locking up the bowels" as it is called, by administration of opiates. Such treatment, of course, results in the formation of hard and large lumps of feces which cause great pain in their passage, and the opiates upset the digestion and cause additional misery to the patient. The whole of this established routine is false in principle and practice. Instead of it he advises the following: On the third day (or fourth if there is no abdominal distention or discomfort) three or four drams of a sterilized soft bismuth ointment is gently injected into the bowel by a rectal ointment repositor and the ointment applied also to the anus. Later a large injection of warm olive oil is given. The evacuation that follows is usually painless and the thick coating of ointment prevents contamination of the sutures. This procedure repeated daily provides for the restoration of the function of the bowel without appreciable suffering to the patient.—*The Clinical Journal.*

Hemorrhage After Operations for Adenoids.—Krebs states that if this complication arises search should first be made to see if any shreds of tissue still remain, and if so, they should be removed. The patient should then be kept flat and absolutely quiet, with the shoulders elevated. Pellets of ice should be sucked, and in order to lessen the blood pressure in the superior vena cava deep inspirations should be taken through the nose, exhalation being gentle and performed through the mouth.—*Centralblatt für Kinderheilkunde.*

Separation of the Urine from the Two Kidneys.—Giordono and Nicolich, of Trieste, have devised the following method for obtaining the urine from either kidney without the use of a ureteral catheter. Giordono observed during a nephrectomy that the urine in the manipulated kidney was pressed out, so that the first urine passed after the operation contained morbid products. Following this hint it occurred to him that the urine might be expressed for diagnostic purposes by massage. The procedure followed by these observers is very simple. The bladder is first emptied, and then one of the kidneys and its ureter is massaged through the lumbar and abdominal regions. The resulting urine in the bladder is withdrawn, the bladder again carefully washed, and the same process applied to the remaining kidney. A number of diagnoses arrived at by this procedure were later confirmed by nephrectomy. The simplicity of this method will commend it to physicians owing to the fact that to catheterize a ureter, especially in the male, requires special skill, and it is a question of grave importance whether or not a catheter after passing through an infected bladder ought to be inserted into a healthy ureter.—*Medical Age.*

A Lubricant for Urethral Instruments.—Strauss recmends the following: 1.5 parts of tragacanth are rubbed up with 50 parts of water, and 50 parts of glycerin are added. The mixture is then sterilized by heat and one-fifth of a part of oxycyanide of mercury is added. The mixture is thick, non-irritating, does not attack the instruments, and makes them very slippery.—*Pharmazeutische Zentralblatt.*

Moist Gauze Dressing.—Experiments by Dr. Noetzels have demonstrated what is well known to surgeons—that the secretions of a wound are drawn up into a moist dressing better than into a dry one. In Dr. Noetzel's experiments virulent anthrax bacilli placed upon an artificial wound in rabbits were absorbed into moist dressings and the infection of the animals was prevented. While both moist and dry dressings were effective in the destruction of germ life, the germs were drawn up into the outer layers of moist gauze, while they were found only in the layers closest to the wound in the dry dressings.—*Indian Medical Record.*

Emergency Treatment of Glaucoma.—Maitland Ramin *The Lancet* says that the practitioner, deprived of expert help, in dealing with a case of glaucoma, ought at once to instill eserine, put leeches to the temples, and apply hot fomentations to the eye. If in a few hours the pain has not subsided, means must be taken to reduce the intraocular tension by opening the eyeball, so as to relieve the strangulation of the corneo-iridic angle. If the practitioner cannot obtain assistance he ought not to wait, but should at once puncture the sclerotic with a narrow knife, and allow some of the vitreous to escape. If he observes strict antiseptic precautions this can be done without danger, and will give relief till the services of a specialist can be obtained. The all-important thing is that the case be taken in time.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cas and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 31, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	387	198
Diphtheria	357	52
Measles	1941	62
Scarlet Fever	220	11
Smallpox	2	.....

A BIOGRAPHIC CLINIC ON GUSTAVE FLAUBERT.

By GEORGE M. GOULD, M.D.,

PHILADELPHIA.

He was a writer of rare talent; had it not been for the nervous disease which seized him at the outset of life, he would have become a man of genius.—Maxime Du Camp.

Writing in their diary in 1863 the brothers Goncourt say that Flaubert told them that when a child he became so absorbed in his reading that he would bite his tongue, twist a lock of hair in his fingers, and sometimes he would fall to the floor. Once he fell against a library window and cut his nose. Both the fact and its significance have been overlooked by the many who have written on Flaubert.

When Flaubert came to Paris to study law, he was 21 years of age, and of "heroic beauty." Many have enthusiastically described the perfection of his skin, head, his "enormous eyes," his hair, shoulders, whiskers, stature, eyebrows; his "trumpet-like voice," his gestures, his laugh; his abounding health, impetuosity, impatience, dominating character, etc. "Gustave was a giant." So physically strong was he that Du Camp says the excesses of his Paris student days knew no limits; he would study all night, run about the whole day, squander energy like a madman, careless of sleep, reckless of every law of moderation or health.

He did not like law, and so little did he care for it that two years later, even with his all-absorbing intellect and splendid memory, he was blackballed by his examiners and he returned, in August, 1843, to his home at Rouen. His irrepressible energy of body and mind, and the inviting opportunities to give it rein in Paris, had saved him from injuring his health, and if his life had been rightly ordered, he might have lived a long, happy, and healthy life. His friend Du Camp says of him that had it not been for the nervous disease which seized him at the outset of life he would have become a man of genius.

In October, two months after Flaubert's return to Rouen, he had what is called his first attack of "epilepsy;" his biographers forget his swoonings, or faintings and fallings, years before and while a child. And they also ignore Flaubert's own testimony as to a nocturnal attack, a month before he left Paris and while studying hard for his final examinations. He remembered that he awoke one morning in a condition of extraordinary lassitude which lasted for a week, and he was sure that this, his "first," had taken place during sleep. Du Camp holds that he was probably right, "because these nocturnal attacks were frequent." "These nocturnal attacks," he continues, "affected him less than the others, bringing on decided fits of misanthropy. Once when he was seized in the neighborhood of Sotteville he secluded himself for several months without going out." There was thus no sudden onset of the disease, as one would believe from the reports, but a beginning in childhood, induced always by excessive reading or study. The frequently described "first" seizure occurred two months after his return to Rouen, while riding in the night with his brother, a practising physician, in a carriage. It was very dark, and in passing a wagon the light flashed in Flaubert's face,* and he fell, unconscious, we gather, and immediately, according to medical custom, was bled by his brother.† Fourteen attacks followed in the next two weeks, probably encouraged by the anemia produced by the terrible bleedings to which parental solicitude and science subjected him. "Excess of plethora, too much energy, and force" said the father, and there was a forbidding of alcohol, of wine, of coffee, of food, and of tobacco. He was stuffed with valerian, indigo, and castoreum. He gulped down the drugs with resignation, ate a little white meat, did not smoke, drank decoctions of orange leaves, smiled, and said Sauterne would taste better. Then he read the books in his father's library on nervous diseases, and said, "I am lost!" Not forgetting the reading, one does not wonder that the treatment kept up the seizures. Du Camp describes a typical example:

"Suddenly, without apparent cause, Gustave raised his head and became very pale; he had felt the aura, the mysterious breath which passes over the face like the flitting of a ghost; his expression was that of anguish, and he raised his shoulders with a gesture of distressing discouragement. He said, *There is a flame in my left eye;* then in a few seconds: *The flame is in the right eye, everything is colored yellow.*‡ Sometimes this peculiar condition lasted for several minutes. It was evident that he hoped the warning would pass without an attack. Then his face would grow still more bloodless, and take on an expression of despair; rapidly he would then walk, or run, to his bed, stretch himself out upon it, gloomy and dejected, as if alive in his shroud, and cry out: *I hold the reins, there is the wagon, I hear the bell,—ah, I see the lantern of the inn!* There followed a harrowing moan the vivid tone of which still vibrates in my ear, and the convulsion followed. This paroxysm into which his whole being entered with fear, was invariably succeeded by profound sleep, and great lassitude for several days."

Dr. Dumesnil, one of Flaubert's many biographers and critics, has written a literary or semimedical clinic, in which he seeks to show that his patient did not have "typical" epilepsy, but that his disease should be called, "Hystero-Neurasthenia." The word raises a smile, and we may pardon the Frenchman's turn for systematization, bringing everything

*Another sign of the ocular origin of Flaubert's seizures is this fact of the influence of light as an incidental cause. In the two attacks, described for us in detail, it was light suddenly flashing upon the eyes and further arousing the irritated surcharged optical centers.

†The poor man seems to have been bled nearly to death, by his father, in every subsequent attack. Once when no blood could be got, his father scalded the patient's hand, inadvertently, of course, in the attempt to arouse circulation and get more blood. The wound was long in healing, and Flaubert carried the scars all his life.

‡If there is any value in the theory of the indication of the seat of the lesion in epilepsy from the peripheral organ first affected, then the ocular nature of the aura in Flaubert's case deserves consideration.

into a *cadre*, or deftly forcing clinical facts into a rigid theoretic pattern. The distinction does not aid us at all to understand either the disease, or its etiology, does not even help us in the simple matter of symptomatology. It is indeed the prototype of a very modern morbid habit among physicians of a certain cast of mind, who cry "atypical" when the particular clinical figure cannot be made to fit into the nosologic puzzle. The more shrewd observer knows that with rare exceptions every case is individual; not even those called infectious and organic are identical in their histories, and when it is a question of functional and psychic diseases, all theories and typicalities end in thin air and ludicrousness. The epileptic seizure in many chronic cases is so uniform that the word typical has been applied to it, but even here there are infinite variations chronicled, while in the early stages, the life-clinic, and the petit-mal types of the disease, there are as many types as there are cases, and there are a thousand atypical examples to one that is properly or foolishly denominated "typical."

Beyond question, Flaubert's seizures will not fit into the crude, "classic," and outworn framework of those lost in the impasse of nominalism, and theory-worshipping. The aura lasted too long, "several minutes," leaving time for speech, gestures, acts, walking, etc. Then there were sentences repeated before the paroxysm. There was no frothing, no biting the tongue. There was long slumber afterwards. There was no mental deterioration, properly speaking, and the disease was at an end in a few years.

So far as we may be certain, there were never any true attacks after those of 1843, except one in 1846. Du Camp spent a part of the summer of 1846 with his friend at Croisset, and nothing is said as to seizures. In May, 1847, the two friends set out from Paris for a walking tour in Brittany, and on the fourth day there was a "crise nerveuse." The famous Dr. Brettonneau was sent for. "He confessed his ignorance and said: Our science is but a series of desiderata, and we have only reached the point of asking what is Migraine?"

This is the first time that this wonderful word has been heard applied to Flaubert's disease.

Du Camp proceeds to say that Brettonneau ordered such huge doses of quinine that even Du Camp objected. To which the physician replied: "Sulphate of quinine is good for nothing if it does not produce in the organism the effect of the shooting a cannon." Whether it was due to the cannon shot or to the ocular rest and the open air active life, there were no further attacks, either of "epilepsy," "hysteroneurasthenia," or even of "migraine," during the four months' tour. We read that the walkers carried on their backs thirty volumes of books!

"When I arrived in Rouen," says Du Camp, "Flaubert's father was bearing a burden of which the effects were seen in his face. One read there of humiliation, despair, and a sort of resignation before a power which he could not conquer. His science was paralyzed before an incurable disease, and his paternal affection suffered because of the powerlessness of his art. The sacred disease, the great neurosis, what Paracelsus calls man's earthquake, had struck Gustave, and brought him to the ground. The poor giant bore the disaster as philosophically as he could. He tried to laugh, or be witty, and to reassure those about him: but he forgot his role, his head fell, and it was easy to see with what his thoughts were busy."

"His nervous malady threw a veil, as it were, over his whole life," and from this time, as he told George Sand, he was "afraid of life." For three years he never went out without a medical attendant, and indeed during his whole life he kept somebody near him. From this cause he hardly ever walked, preferring a carriage, and his fear degenerated into a strange rule of hygiene that walking itself was hurtful. He retreated not only into solitude, but into himself, and, with the exception of the noise he himself made, his mother's care was to envelop him in an atmosphere of perfect calm. She watched over him all her life, looking for the slightest symptom of ill-health, and at every unusual noise or silence she would run to the door.

To the trained oculist who has cured a number of epileptic patients, it matters not what name is tacked upon the clinical facts; and to one who seeks the single cause of the individual case of disease, or the pathogenesis of the affection generally, such meticulous foibles provoke either mirth or disgust, possibly both.

All such puerilities are, or should be, forgotten in Flaubert's case, because of the tragedy that followed the first attacks. Instead of a joyous, expansive, energetic, exuberant healthfulness of mind, there was gloom, silence, self-repression—a most morbid psychosis. Previous to this time he had played the dilettante with the poison of pessimism: he had tasted and tested it in jocular mood; he now fed upon it, and it bit into every cell of his body, and attended every stirring of his psyche.

> This disease shattered his life, rendering him solitary and unsociable. He did not speak of it willingly, but in strict confidence he did so freely. Never was he known to mention the true name of his affliction, but alluded only to his "attack of nerves." (Du Camp.)
>
> I have had two distinct lives * * * my active, emotional, passionate life, filled with somersaults, contradictions, and manifold sensations, came to an end at the age of twenty-two. (25.)

Even among physicians few were better equipped as regards medical science than Flaubert. It is therefore of interest to see how he looked upon his own case. The following excerpts are illustrative:

> You ask me how I cured myself of the nervous hallucinations from which I formerly suffered? In two ways: (1) By studying them scientifically, that is to say, by trying to understand them; and (2) by force of will. I have often felt insanity coming upon me. There was a whirl of ideas and images in my poor brain, in which my consciousness, my *me*, seemed to founder like a ship beneath a storm. But I clung desperately to my reason. It prevailed over everything though besieged and beaten upon. At other times I used to try, by means of imagination, to give myself these horrible sufferings factitiously. I have played with madness and fantasy like Mithridates with the poisons. I was sustained by a mighty pride, and I conquered the mischief by wrestling with it. (36.)
>
> He spoke correctly when he said, "I am the Victim of Physiology." (Du Camp.)
>
> There are only two or three years (from 17 to 19) in which I have lived in full. * * * Since then I have deteriorated furiously; some mornings I am frightened at myself, I am so wrinkled and used up. * * * But I do not regret my youth. I was atrociously weary, I dreamed of suicide! I was devoured with every kind of melancholy. My nervous malady has done me good, for it brought all this down to the physical basis and left my head cooler, besides making me acquainted with curious psychologic phenomena of which no one has any idea or rather has never felt. (32.)
>
> In my youth I was horribly wearied, I dreamed of suicide, I consumed myself in all possible kinds of melancholy; my nervous malady did me good, it diverted all that to the physical element, and left my head cooler, and then it introduced me to curious psychological phenomena, of which no one has any idea or rather which no one has felt. I will take my revenge some day, I will utilize them in a book (referring to *St. Anthony*), but as it is a subject which frightens me, speaking from the point of view of

health, I must wait in order to be able to give these impressions to myself artificially, ideally, and so without danger to myself or my work. (32.)

My nervous disease was the froth of these little intellectual facetiæ. Each attack was a kind of hemorrhage of innervation, seminal losses of the picturesque powers of the brain, a hundred thousand images springing at once like fire works. There was an actrocious tearing of the soul from the body (I was many times convinced I was dead), but my personality, the essential, rational being held out to the end; without this suffering I would have been worthless because I should have been purely passive, and I always retained consciousness even when I was unable to speak. (32.)

I also had my nervous period, my sentimental epoch, and like a galley slave I have its scar on my neck. With my burned hand I have the right now to write concerning the nature of fire. (31.)

But the old secret appears at times, the old misery of which no one knows, the profound wound always concealed. (33.)

Add to this my attacks of the nerves which are only involuntary declivities of ideas and images. (31.)

I have had a great deal of experience with neuroses. All treatment ordered in these conditions only makes the evil worse. I have never met a single physician intelligent in these things—no, not one. This is consoling. One must study himself scientifically and experiment as to what is the best thing to do. (50.)

When he told me that I had "a disease of the spinal cord, a softening of the brain," it made me laugh. 1853.

If I had had a sounder brain, I should not have made myself ill over reading law, and wearying myself. The vexation instead of staying in my head, passed into my limbs, and made them writhe with convulsions. It was a deviation. (31.)

In the last quotation we see an acuteness of observation and a soundness of judgment which no physician of that day could have equaled. There is a flashing glimpse into the physiology of epilepsy. If some of our modern epileptic specialists had either the desire or the ability to look at the disease in such a physiological and rational way, we should be much nearer a solution of the terrible problem. To the irritation of reading he ascribes the source of his ill—in a half-blind way, of course, and yet clearly, and his *deviation* is a good statement of the explanation of the storm of derouted reflex irritation submerging the lower centers.

In 1851, at the age of 30, when Flaubert's solicitude and fright as regards epilepsy had somewhat subsided, he wrote the following remarkable sentence:

The secret of everything which surprises you in me, dear friend, is in this part of my private life which no one knows. The single confident which it had was interred four years ago.

Five years before this, and while he was still under the terrifying influence of the shock, he was compelled to go to Paris on some business connected with the death of his father. A medical attendant accompanied him every instant. His friend, Du Camp, says of him during this visit, that he passed rapidly and without apparent cause from a state of excitement or exaltation to that of depression, that of normal health being almost unknown. He either walked so swiftly that his friends could not keep up with him, or he slept so soundly that it was almost impossible to awaken him.

This description appears to me to have a significance which is simply amazing. And it is quite as astonishing that a multitude of writers, medical and literary, have wholly neglected it. Writing four years previously he says that his "secret" was known to only one person who died "four years ago." There is but one explanation of these things, and of many such mysteries one need not recount, and especially of the character of *St. Anthony* of the "second style" or making, etc. There is no clinical explanation of all these facts, except upon the supposition that since the "earthquake" of 1843, Flaubert was constantly under the influence of opium. In 1853 Flaubert wrote that he had often heard his father credited with a comprehension or diagnosis of diseases without understanding the reasons whereby he reached his conclusions. One cannot be sure that Flaubert's mother did or did not, also know the "secret." There is no reason why the world should not know it, and one may hope that documentary proof may sometime transform my theory into history. It certainly throws a flood of light into a hundred puzzling mysteries, and solves many of the enigmas of his character, life, and literary workmanship in a most gratifying manner.

And especially as to the choice of subject, method of out-working, etc., of the morbid piece of literature, the second *Saint Anthony*, which he composed during the years preceding the journey to the Orient. A study of that book will make more clear Du Camp's correct observation, that "Flaubert's faults were especially the consequences of his nervous ailment, without which his talent, his habits, his character remain inexplicable."

"At the age of twenty," writes Du Camp, "Flaubert had an exceptional intellectual development; he was very peculiar, highly original, open to the world and appropriating everything with extraordinary rapidity. His reading had been extensive, and his memory was well-stocked. He worked with ease, and he was naturally fruitful, like a good tree planted in fat soil and grafted with a master hand. * * * But now Flaubert stopped. He explained his loss of memory as due to the abuse of quinine with which he had been stuffed. His former large curiosity was stifled, he narrowed his field of action, and limited himself to the revery of the moment. For months he never read a journal, and would not allow any one to speak of the external world. Real life was put out of his thought, and he seemed to float in a continuous dream from which he was aroused only with effort."

When the plan of an oriental journey had been agreed upon Flaubert delayed it until he should be able to complete the *Saint Anthony* upon which he had been working with great zeal for several years. At last it was ready, and the decision as to the worth of the great enterprise was to be left to his two best friends. So sure was Flaubert of their opinion that before he began the reading to them he waved the pages above his head and cried out: "Now, if you do not howl with enthusiasm, nothing is capable of moving you." The patient friends listened in silence for four days, eight hours a day, thirty-two hours in all! What could the poor judges answer the eager questioner?

"Phrases, phrases, beautiful, expertly constructed, harmonious, often redundant, made of grandiose fancies and of peculiar metaphors,—but only phrases, which might be mixed and transposed, without changing the book as a whole."

"Useless work! We could neither comprehend, nor guess whither it all tended, and in fact it arrived nowhere. Three years of labor without result! * * * We judged that the thing should be thrown into the fire and never spoken of again. Flaubert leaped up and uttered a cry of horror."

"You are perhaps right;" he said to us: "by absorption in my subject I have been fascinated by it and have not seen clearly. I admit the faults you speak of, but they are inherent in my nature; what is the remedy?" The renunciation, we said, of such vague subjects, the renunciation of lyricism, and the choice of a subject in which lyricism will be ridiculous.

He often said to Du Camp: "I was diseased with the cancer of lyricism; you operated upon me. It was high time, but I shrieked with the pain."* Later Flaubert frankly confessed that in *Saint An-*

*This, be it noted, was the *Saint Anthony* of the second overworking. If that of the third revision long after the "operation" is now recognized as so worthless, what must have been the quality of that of the "second style!"

thony he was "himself the Saint, and I forgot it." And the Apostle of the objective in art voices piteously his fall in the mud of disappointment. In 1853 he writes:

"I feel more and more funereal. My novel gives me cold sweats; sixty-five pages in five months! Oh, the joyful times of *St. Anthony*, where are you? I then wrote with my whole being!" (32.)

"I know those masked balls of the imagination, back from which one returns with death in the heart, exhausted, tired out, having seen only falsity, and indulged only in follies." (32.)

"*St. Anthony* was an experiment. It was a subject in which I was entirely free, as regards lyricism, movements, extravagances. I was writing according to my nature, and had only to go straight on. I shall never again find those recklessnesses of style such as I experienced during those eighteen months as I joyously chose the pearls of my necklace. I forgot but one thing, the cord."

In one word, *The Temptation of St. Anthony* was a prolonged opium dream. His reason, the instrument of differentiation, precision and limitation, was in abeyance, was submerged in hypnotic paralysis, and his exuberant imagination was allowed unrestricted play in a realm of fancy, tradition, myth, and metaphysical moonshine. From this he returned to the common world, freed, at least in part, from the drug habit. He then seems to have acted upon the advice of his friend and chosen a subject in which lyricism would be both impossible and ridiculous. *Mme. Bovary* was the pattern and ideal of the "realistic novel." He had no creative ability, and so this work is a sort of microscopic photograph in which there is little of value except the polishing of language, perfection of phrase, and the consecration of style. The tremendous contrast between the exuberance of all that preceded *Bovary* and all the pitiful, petty misery that followed after *St. Anthony*, an irritating puzzle to his biographers and critics, did not escape the attention of Flaubert himself:

A bad week, work would not budge; I reached a point where I knew not what to say. Everything was nuances and refinements in which all was black, and it is impossible to make clear by words what is obscure in the thought. I have sketched, bungled, floundered about, groped. I may find myself at last. What a scamp is style! You have no idea of this worthless book. As much as I have been open-breasted in my other books, by so much have I in this sought to be tight-buttoned and to follow a straight geometric line—no lyricism, no reflections, the author's personality not to be found. (31.)

There are in me, speaking in a literary sense, two distinct fellows, one who is smitten with *gueulades*, lyricism, the eagle flight, all the sonorities of rhetoric and the summits of the idea; the other who fathoms and excavates truth to the extent of his ability, who arraigns the tiny fact as relentlessly as the great one, who would make you realize almost *materially* the things he produces. (31.)

In my youth I had great belief in myself, superb leaps of the spirit, impetuosity in my whole being. I dreamed of love, of glory, of the beautiful. My heart was as large as the world, and I breathed all the winds of heaven. Then, little by little I hardened and shriveled up, worn out, withered. (36.)

There are times when I believe that I am wrong in trying to write a rational book, and not abandon myself to all the lyric extremes, violences, philosophies, fantastic eccentricities that come into my head. (30.)

Even at the age of 18 he correctly describes his natural proclivities:

I incline to facetiousness, to intemperance, to extravagances, the pell-mell of rummaging, without order, without style, etc. (18.)

And in the heart of the *Bovary* period his sighs are still heard:

I love the trenchant and demoniac geniuses; one does not accomplish great things without fanaticism. (32.)

Exuberance—that is what charms me. (34.)

But exuberance was impossible after the opium-years of *Anthony*, and as creative ability had been denied the writer, there could remain only a wearying, ruinous, and impossible striving after perfection of style, elaboration of phrase, ending in a pessimism which is absolutely unrivaled.

Some one has said of Flaubert that "he had a sort of impossibility of happiness," but that superficially cynical criticism needs to be placed over against the pathetic groan of the sufferer toward the end of his life. *How is it possible to be not sick?* Much, indeed all, should be forgiven those who have much suffered. Early his pain began, it was, with few and short exceptions, continuous, and its ingravescence ended with an early death:

Why this happiness? What is it afflicts me? (18.)

A man sick half of the time, and so depressed the other half that he has neither the power nor the intellect to write even the most commonplace letters. (23.)

My nerves leave me little rest. (23.)

By dint of expanding itself to suffering, the soul attains to a prodigious capacity for it. (25.)

Men like me are sick in vain because they cannot die. (25.)

It is the road of death, and I want to live still to make three or four other books. (32.)

My weariness cannot be greater. (32.)

Laxatives, purgatives, derivatives, leeches, fever, diarrhea, three sleepless nights, outrageous stupidity of the bourgeois, etc., etc.,—such has been my week. (33.)

I am profoundly sick without any being knowing how. I cough, and spout continuously like a whale. Add a depression that is unconquerable. I am melancholic, etc. (47.)

My head is very much fatigued. It is useless for me to try to work; the thing will not go. Everything irritates and wounds me, and although I am able to control myself before people, I have from time to time fits of weeping in which it seems as if I should break down. And now I have an entirely new symptom—the approach of old age. (40.)

How tired I am! I would like to go away where I should hear nothing spoken of. (50.)

Flaubert was so irascible, biting, etc., that it seemed as if he must be attacked with the morbid irritability of all the nervous diseases in their germ. (*Goncourts.*) (51.)

What have I not endured for four months! I do not know what has been going on within me, but it is certain that I have been very sick. (52.)

In the depths of pain in every part of my old machine. (53.)

For six months I do not know what ails me, but I feel profoundly ill without being able to say in exactly what way. (54.)

Flaubert not here; sick in bed. (*Goncourts.*) (54.)

It grows worse and worse with me. I have no idea what is the matter, and no one knows. The word neurosis expresses a group of varied phenomena plus the ignorance of the physicians. I am advised to rest; but how? To take things easy, to avoid solitude, etc., all of which are impracticable. There is only one remedy—time. If after a month's rest I do not feel better, I will try the remedy of Charles XII., and remain in bed for six months. (56.)

I am hurrying; I shake myself so as not to lose a minute. Even my bones are tired. (59.)

There are times when it is difficult for me even to lift a penholder. (59.)

The dependence of suffering upon use of the eyes is capitally illustrated in Flaubert's case. I might have made hundreds of excerpts besides the following:

I have no heart to work at anything whatever. You know that we all have strange moments of weariness; life is so heavy that even those for whom the burden is least weighty often sink beneath it. A week ago I laid aside historical studies—and for what? I do not know. I have scarcely the heart to smoke, and I am filled with a great weariness. It is strange, for two weeks ago I was in the best of health. This change is perhaps the result of the kind of work I have been doing for some time. (17.)

I am not made to enjoy. (25.)

To think is to suffer. (25.)

Those excesses in the matter of work, which exhaust, and by reason of that fatigue which they entail, make you lose more time in the end than you have gained. (25.)

You must know that I am driven wild by writing; style, which is a thing that I take very much in earnest, agitates

my nerves horribly. I vex myself, I prey on myself, there are days I am quite ill from it, when I am feverish at night. (25.)

Sometimes one rejoices hugely at success in composition, but this pleasure is bought at the cost of how much discouragement and bitterness? (25.)

You were sick; do not work to excess which exhausts you because of the weariness; you finally lose time which you thought to save. (25.)

I am harassed by my writing; style shakes my nerves horribly. (26.)

My writing does not put me in a normal state. * * * I am furiously tired; sometimes there is a doubled lassitude just as after dinner one wants to vomit. (26.)

From April, 1848, to May, 1849, there is a gap in the correspondence. At this time Flaubert was working hard at the *St. Anthony,* and his health had failed again. (*Tarver.*) (28.)

I left you with laughter in my mouth and gaiety in my heart, and now I am frightfully despairing. What a difference in three days! I know that my happiness left me in returning to Rouen, and taking up the work of each day, the life of minutiæ, the writing table, etc. (29.)

For three months I have been writing every day from morning until evening. I am at my wits' end with the ceaseless irritation of the incessant impossibility of completing my task. (29.)

Who knows if I shall not become a Cretin in four years! (30.)

For the seven or eight days in which I have been busy at these corrections my nerves have been terribly on edge; I hurry, and such work must be done slowly. (31.)

This book tortures me to such a degree that sometimes I become physically sick. For three weeks I often have pain sufficient to make me swoon. At other times I am oppressed, or come near vomiting. I think I should have hanged myself to-day had not my pride prevented. If I cannot finish *Bovary* in fifteen days I shall stop work indefinitely and until I find again the desire to write. I am too irritated, irritating, sullen, etc. (32.)

After great excitement from long-continued writing I have great pain in my knees, my back, and my head, lassitude, etc. (32.)

My head is afire; and because I have written too long,—from noon until midnight. (32.)

I must love you or I could not write, because I am exhausted. I have an iron band about my head. I have written for twelve hours, etc. (32.)

How I suffer! It is a thing atrociously delicious to write and to torture oneself in this way. There is a mystery here which I do not understand. (32.)

To suffer and to think—are these the same thing? (32.)

The week has been bad; I have writhed with exhaustion and abundant disgust. This happens regularly when I have finished something and must go to work again. (32.)

I am overwhelmed. My brain dances in my head. From six o'clock yesterday evening until now, one o'clock, I have copied seventy-seven consecutive pages; it is brutalizing. I have crushed the branches of my cervical vertebræ from bending my head too long. (32.)

Writing brutalizes me. I feel toward literature the hatred of powerlessness. (34.)

I cling to my chimera of style, which wears me out body and soul. (34.)

Since Thursday I have been in a frightful state of weariness and weakness, the result of a paragraph which I could not finish. This book crushes me, and I use up the remainder of my youth in writing it. (35.)

I must have a herculean temperament to withstand the atrocious tortures to which my work condemns me. (36.)

The more expert I become in my art, the more this art becomes a torment. Imagination stands still and taste grows. (36.)

Few have suffered more than I for the sake of literature. (36.)

I work away stubbornly and then am unable to sleep for two days. At last I finish my unfinishable Chapter VII. (39.)

For a long time I have been training my nerves; sometimes they get angry, and then they disorder the whole machine. (40.)

My wretched book has exhausted even the marrow of my bones. I am used up. (43.)

I read your book for four and a half hours and then did not sleep that night, and I had the stomach trouble. You will cause much gastritis. What a frightful book! If I were not suffering so to-day I would write you a long letter. (44.)

I am working like thirty thousand niggers. * * * Some days I feel as if ground up. I can hardly stand, and intermitting suffocations stifle me. (47.)

It is always so when I set to work. Then I am wretched, wretched, wretched! But this time it is worse than ever before. (48.)

I have been much weakened all this week in which I have written nearly one page. (52.)

Strange things are taking place within me. My psychic weakness must have a secret origin. I feel old, discouraged, used up. Perhaps it is my work which makes me sick, for I have undertaken a senseless task. (54.)

For the last four months, in which I have endured infernal anguish, I have in all written four pages; and bad ones they are. My poor brain cannot withstand another such injury; this grows very clear to me. (54.)

Physical fatigue prevents me writing every day. (57). 1878.

My furious labor brought on what Dr. Trelet calls *la folie lucide.* (57.)

Lest one should carelessly repeat the careless error that mental labor may produce suffering even with healthy eyes, it need only be recalled that that foolishness has long ago been outlived. There are a number of answers to the "brain-fag" philosopher. There are few eyes without some refractive error, and even with least, an immense amount of labor, may produce great suffering. In Flaubert's case the disproof is perfect, because he found his mind worked well and painlessly when he lay down and closed his eyes.

Then there is the striking fact that when he was walking or journeying, all pain, and even all pessimism disappeared as if by magic:

My health, far from bettering, is worse, and I was compelled to consult Dr. Cloquet at Paris, who emphatically urged me to live in a warmer climate. I leave for Egypt in October. (27.)

He was not seasick, but for the eleven days of the sea-voyage he ate, smoked, joked, and was genial, with his stories, wit, good spirits, etc. (28.)

I have become enormously fat in the East. (29.)

As to health it is excellent. We are all getting fat. (29.)

In Egypt he says:—What we need, in writing, is the soul of the matter, the idea of the thing. * * * All our learning,—of what use is it? But the heart, the life, the sap? Whence to set out, and where to go? Oh, when I get back, I shall take up once more my old tranquil life at my writing table, etc. (29.)

Why was I so happy and healthy in Egypt? (32.)

Yesterday and to-day I slept like a drunken man all the afternon. I had the feeling as one has after drinking six bottles of brandy. I was stupid and dazed. But this evening, after dieting all day, strength has returned and I have written almost in a breath a whole page of close psychologic reasoning. (32.)

After the journey to Trouville, he writes: What a volume I could make this evening if expression were as easy as thinking! (32.)

I advise you to travel and you say your health does not permit. But it is precisely for your health that you should change your life. (36.)

In Africa: I sleep like a stone, eat like an ogre, and drink like a sponge. You have never seen me while traveling,—then everything goes well. (37.)

I have recovered from the frightful blow which *St. Anthony* gave me. I do not boast of not being a bit dizzy, but I am no longer sick. * * * Has there been some progress in me? From day to day I find myself more sensitive, more easily moved. (37.) (On his way back from the Orient.)

For five months I have been in a deplorable condition, and if I go on this way the work will not be ended in twenty years. I must positively take a journey in Africa. (37.)

It was high time. In the six months since returning from the Orient I have stifled. (37.)

My four weeks at Vichy were stupid, and I did nothing but sleep. Doubtless I needed it; it refreshed me. But my intellect is atrophied. (39.)

The excitement of bringing out *The Candidate* told severely on Flaubert's nerves, and he consulted a doctor, who recommended a Swiss town. (53.)

Did I tell you that I should go this summer and set up my nerves at St. Moritz? It is by the advice of Dr. Hardy, who calls me an hysterical old woman. (53.)

I shall soon spend a few weeks on the Righi to deneuropathize myself. (53.)

To Switzerland by my physician's orders. (53.)

At Kalt-Bad for 15 days, and bursting with ennui because I have brought no books or work with me. I am thinking of myself, and when one does this he will end by becoming really ill. (53.)

Righi, where I nearly died with ennui, did me much good. My troubles have lessened, and I am able to go upstairs like a young man. I shall now return and go at my novel, which will take me two or three years to complete. (53.)

As it is absolutely necessary for me to get out of this condition of agony, I shall in September go to Concarneau. (54.)

I have been at Concarneau for 15 days without being absurdly well. I am in a more calm condition. (54.)

Since I have tried hydrotherapy I find myself calmer and am going to work again without looking behind myself. (54.)

I have worked this winter in a most reckless way and reached Paris in an absolutely lamentable condition. I am a little better. (55.)

I am just back in the old house which I left last year, three-fourths dead with discouragement. Things are not indeed superb, but they are perhaps tolerable. I am re-equipped and I wish to write. (55.)

At first glance it might seem that Flaubert's complaints of ill health, pessimism, etc., began too early in life to be caused by eyestrain, and that they arose in some precedent or more fundamental morbidity of his nature. "I cried too much in my youth to sing now; my voice is hoarse," says the young man of 25. We must not forget that as a child he was so preoccupied in his reading, read so long and so intensely, that he frequently fell over in a swoon. The boy of 10 wrote "tragedies," and when he was just 9 years old he writes to a boy friend:

I will send you some of my political liberal speeches. I will also send you some of my comedies. If you wish us to join writing, I will write comedy, and you shall write your dreams, and as there is a lady who comes to our house, and who always talks silly things to us, I will write them.

And at 13 years the true note is struck:

As for us, let us concern ourselves with art, with art, that is greater than peoples, than crowns and kings, always there, floating on enthusiasm, with her heavenly diadem.

Observant and keen oculists have often noticed a common symptom in the stories of their patients. There are many ways of expressing it—"everything stops," they repeat; "while I am writing or reading, things stop," "I get blind spells," "I half lose myself," "I get dazed," "I seem stupid," "I can't see," "everything becomes blank," "I have to quit and go take a walk," "my mind won't work," "I sit like a fool," "things fade out," "I lose my place," "the letters blur up"—and a thousand such expressions. Carlyle would sit for hours staring at his paper in blank amazement and thoughtlessness. In the letters of nearly every great eyestrain sufferer we find this symptom constantly reappearing. It is illustrated with most striking insistence every day that Flaubert drove his baulking eyes to their savage work. It begins as early as 18 and is clearly stated in a thousand passages I have not transcribed. The following are examples:

Formerly I thought, reflected, and wrote, good and bad thrown recklessly upon paper, so uncontrolled was my fervor; now I no not hink, meditation has gone, and I write nothing. My thoughts are confused, I am incapable of any imaginative labor, and everything that I write is dry, painful, forced, and extracted with suffering. I began a recondite work a couple of months ago, and all I have done is absurd, without the least idea in it, and I had to stop. (18.)

The further I go the less capable I find myself of expressing the idea.

Two execrable days. It is impossible for me to write a line. How I have sworn, spoiled paper, stamped with rage.

I always am frightened when I go to write. In beginning a work, do you also experience a sort of religious terror, an apprehension in commencing the dream? (25.)

Sick, irritated, the prey a thousand times a day of an atrocious agony. It was not like this formerly. (25.)

Already my imagination dies down, my power weakens, and my phrase disgusts me, and if I keep what I write it is because I love to surround myself with memories just as I do not sell my old clothes. (25.)

If you knew all the invisible bands of inaction which are about my body, and all the fogs which obscure my brain! I often feel a deadly fatigue of ennui upon being compelled to do the simplest thing, and it is only by great efforts that I am able to seize a clear idea. My youth steeped me in a sort of opium of weariness for my whole life. I hate life. It is torment to eat, to dress myself, to stand up. I have felt it everywhere and in everything and throughout everything—at college, at Paris, Rouen, the Nile, on the voyage. (30.)

I must keep the most complete immobility of life in order to write. I think better lying on my back and with my eyes closed. (31.)

I assure you I have fear now (of madness), but in seating myself at the table to write to you, the sight of the white paper has calmed me. (31.)

At work the whole week on *Bovary*, mad at not being able to make any progress. (31.)

I do not know if it is the Springtime Season, but I am in a frightfully bad humor, and my nerves are as irritable as wires. I am in a rage without knowing why. Perhaps it is all caused by my novel. It does not budge, will not go on; I am more weary than if I were rolling mountains. At times I almost break into tears. A superhuman will is demanded to write, and I am only a man. It seems occasionally as if I needed to sleep continuously for six months. I have written only 20 pages in a month, working at least seven hours a day, and the result of it all is bitterness, inner humiliation, my only reliance the ferocity of an unconquerable fantasy; but I grow old, and life is short. (31.)

Sometimes my arm almost falls with weariness, and my head is lost in vagueness. I live a bitter life, without external pleasures, and the only thing that keeps me up is a kind of continual raging, that weeps often because of powerlessness, but which never stops. I love my work with an unbridled and perverse zeal, like an ascetic. The hair-cloth scratches my body. Sometimes, when I find only inner vacuity, when expression is denied, when after long pages of scribbling I find I have not worked out a single phrase, I fall on my lounge and rest there, stupid and in a subjective desert of ennui. (31.)

I have succeeded in writing but one scene in four months. (32.)

For three days I have rolled among my furniture in attempting to find what to write. There are cruel moments in which the thread is broken and the reel unwound. * * * The end of my book is postponed, and it may prove the end of my own life. * * * Everything comes out of the head, and if that miscarries, it was at least good gymnastics. What is natural to me is unnatural to others, is extraordinary, fantastic, metaphysical howling, mythology. *St. Anthony* did not give me a quarter of the mental tension which *Bovary* causes. It was an outpouring; I had only pleasure in writing during the eighteen months of its composition. Its five hundred pages were the most profoundly voluptuous of my life. I now have to get within the skins of those antipathetic to me, and for six months I make platonic love while I am exalted as a Catholic at the call of the bells and want to go to the confessional. (32.)

My head whirls and my throat burns because I have hunted, chopped, dug, gone over again, rummaged, and howled, in a hundred thousand ways, a phrase which at last I have finished. (32.)

I am broken-hearted with weariness and humiliated with weakness. Ideas will not come; in vain I dig in my head, my heart, and my senses, nothing anywhere. The whole day has passed thus and I have been unable to write a line, not even think a thought, or find any activity. Utter emptiness and void. (32.)

My head swims with stupidity, discouragement, and fatigue. I spent four hours without achieving a single sentence. To-day I have not written a line. What atrocious labor, what exhaustion! O Art! Art! what is this mad chimera which eats the heart, and why? What a fool is one to give himself such suffering! (32.)

For four days I have had fever, and yesterday it was violent. (32.)

You do not know what it is to remain a whole day with your head in your two hands, trying to squeeze a word out of your wretched brain. (45.)

You understand nothing of my literary torment. I do not know how to go about it to write. (45.)

As for literature, I am incapable of any work. In about four months (during which I have been in hellish anxiety) I have written fourteen pages in all, and those bad ones. My poor brain will not stand such a blow. That seems to me quite clear. (54.)

In a strictly scientific and medical sense, we have here a capital example of what the physiologists call inhibition. A common function is prevented by some reflex which prevents its execution. A subconscious wisdom forefeels the hurt and shrinks from it. The sick lose the spur of action, even the desire for it. The wounded or weak animal feigns death; the hurt eyes notify the brain to stop, and the very effort required to overcome the strain checks mental activity and initiative. It is such a natural, common, and necessary protective method that we have overlooked it. But what vast significance it has for the welfare of the individual literary worker, and for literature itself. It is extremely frequently that in this simple inhibition of thought due to eyestrain lies the entire question of the quality of "inspiration" and of "inspiration" itself. Whipping oneself into "a white heat," as Carlyle and others did, or developing the aphorism-style of Nietzsche, with its morbid vagueness, excess, and disjointedness, give an altogether diseased character to the literary work .There is, indeed, often tragedy to the worker and to his literary art in not having a normal and physiologically acting ocular mechanism. Of all truths none is truer than that healthy and happy brain-action often depends upon spectacles which give health and ease to ocular function. Forcing inspiration defeats its own object and results in sterility. In the heart of his *Bovary* period Flaubert ground up his soul in agony and fury to overcome this inhibition. He is said to have hunted for one desired word for three weeks. "How tormenting is my *Bovary!* I want to cry sometimes, so much do I feel my lack of power. But I'd rather die than play the juggler with it." And so he stamped and walked, howled, sang, and declaimed, like a madman day and night for thirty years to lash himself into a fury and overcome the inhibitional effects of eyestrain. He could lie down, close his eyes, and his brain would work vividly, and he could go on travels and his mind at once became a fireworks of abundant energy. But sit at his table and write—that he could not do. *St. Anthony* drew its inspiration, as I believe, from opium, and the awful pain of the undeception resulting from that error was never for a moment forgotten by Flaubert. Creative ability was denied him by nature, and if there was any that slipped through the fingers of the Fates, it was paralyzed by disease and fear, or exhaled into dream by the hypnotic. What was left? The labor of days over a sentence, the desolate and empty beauty of cadenced prose, the "filing of the line" until it was a line—geometrically speaking—that is, without breadth or thickness. At its best only esthetic mysticism could result, at its worst, pessimism relentlessly and logically intermixing, what Gautier called the *triste amour du laid*, "the pitiable love of the unlovely." His own poor mother at last said to him, "The mania for phrases has dried up your heart." His own self-judgment was that he had no interest in the external, in useful things. "I have bid practical life an irrevocable adieu." Some of his rules of literary workmanship, or their consequences, are these:

The whole United States may perish rather than one principle. May I die like a dog rather than hurry a second the phrase which is not ripe.

His great principle now, was that the utmost weakness was to show one's personal feelings in the art work.

I have always forbidden myself to put anything of myself in my writings, but have nevertheless done so.

The idea exists only by virtue of its form.

The men of olden times had no diseases of the nerves such as I have.

Physically speaking, for my health's sake, I need to reinvigorate myself with good poetic phrases.

For fifteen long years I have labored like a mule. I have lived all my life in this maniacal obsession to the exclusion of my other passions, which I shut in cages and which I went to inspect occasionally to amuse myself.

If I have the power I have not the patience, and patience is everything.

What would be fine and desirable would be a book upon nothing at all, a book without exterior bonds, which would upbear itself by the internal force of its own style, like the earth without support in the air, a book almost without subject, or at least where the subject was almost invisible, if possible. The most beautiful works are those having the least of material; the more that expression comes near to being thought, the more the word adheres to it and disappears, the more beautiful it is. I believe the future of art is along this road.

Style is in itself and exclusively an absolute method of seeing things.

The moment a thing is true it is good.

Now what in the person, and in his art-work, and in his philosophy, was the conclusion of the whole matter? The latest and perhaps the best answer is, Zolaism. But the ideal is sought by thousands of other errant pseudoliterateurs that tell their wearisome story in every bookstall and "popular" magazine of the day. It is, strangely enough, a result of diametrically opposed and opposing tendencies, disease being the father of both—"Art for art's sake," and "form," empty and contentless; or Zolaism—the formless search for "truth"—the latter day alias of mud and filth, shortly, the yellow newspaper. Both vicious bastards have for their father Flaubert's monotonously repetitive "Art has no morality," leaving the "artists" to be impaled on either horn of the dilemma. They usually succeeded in being doubly gored. Already Flaubert recognized the fact in himself when he said, "The basis of my character, whatever is said, is the mountebank"; and in the further statements:

I hate what it is agreed to call *realism*, although I am made one of its pontiffs.

When Zola shall give me the definition of the term *Naturalism*, I shall perhaps be a Naturalist. But until then I do not know what it means.

They would use Mount Olympus for a potato patch. (1846.)

"I am the last of the Church Fathers," he said a few years before his death.

Du Camp, in allusion to his friend, says that the restless search for the exquisite finally ends in all sensation becoming almost pain. So dissatisfied was Flaubert with his (the greatest Master's) most excessive and most perfect work in "style," that he wished to buy up all the copies of *Bovary* and suppress the publication. *Anthony* had proved a hypnosis dream. Salambo, "an orgy of antiquarian erudition." How was it with the method itself?

I have suppressed phrases at the end of five or six pages which have cost me the work of entire days.

Sometimes one realizes that he needs to make himself suffer, to hate his own flesh, to throw mud in his face, so hideous does it seem. Without the love of form I should perhaps have been a great mystic.

This book, which is only style, has for its constant danger style itself. The phrase intoxicates me, and I lose sight of the idea.

The deplorable mania of analysis exhausts me. I doubt everything, and even my doubt. You thought me young, and I am old.

As I approach mastery, the art of writing appears in itself more impracticable and I am more and more disgusted with anything I produce.

The plastic art of style is not as large as the entire idea, I well know, but whose the fault? Language; we have too many things and not enough forms, whence the torture of the conscientious. (1853.)

After all the struggle and the "success" there is the most pitiful failure: *"Form is only an error of sense, and substance a fancy of your thought."* A faint and far forefeeling of a greater truth is dimly seen in his saying:

The blood of the Middle Ages still pulses in the veins of humanity, and it pants for the mighty air of future centuries, which only bring it storms.

In the score of clinical biographies I have collected it is a rule, almost absolute, that the general pessimistic view of a writer depends accurately upon the persistence and intensity of the suffering from eyestrain, and the most extreme and maddest expressions come from a special day or hour of ocular and nervous injury. This rule is admirably illustrated in Flaubert's case. The Goncourts say that Flaubert told them that it was indignation alone that kept him alive. Over his own tomb might have been erected Goya's monument, a skeleton crawling out of the grave and scrawling on the wall, *Nothing*. I choose a few lines:

There is left only weariness during life, a tomb after death, and rottenness for eternity. (18.)

Vice wearies me as much as virtue. (18.)

Let us spit on their heads, and then calmly continue our task. (21.)

The modern weariness that gnaws a man's entrails and turns an intelligent being into a walking shadow, a thinking apparition. (24.)

Real griefs stay in my heart, bitter and hard; they crystallize as they come. (25.)

There is no springtime in my heart.

If I had expected better things of life I should have cursed it. (25.)

I have never seen a child without thinking it will become aged, nor a cradle without seeing a grave. (25.)

You seem to be happy; that is sad. (25.)

The burden of great despair that nothing lightens. (25.)

I now see my maturity bordering on decay. (25.)

I have never had a sentiment that I have not tried to be done with it. (30.)

I mock at everything, even at those I love most. (31.)

I was born with a heap of vices which have never even looked out of the window. I love wine and do not drink. I am a gambler and have never touched a card. Debauchery attracts me, but I live like a monk. I am at bottom a mystic, but I have no faith. (31.)

Happiness is an invention of the devil in order to make the human race mad. (32.)

The love of humanity is as sorry a thing as the love of God. (32.)

If I ever achieve any success I shall greatly regret it. (32.)

Despair is my normal state. (36.)

What a city of the dead is the human heart. (36.)

Paganism, Christianity, Smuggery. These are the three great evolutions of humanity. It is not pleasant to find one's self in the last. (50.)

The odor of corpses disgusts me less than the miasm of egotism breathing from all mouths. (50.)

The mass, the number is always idiotic. (50.)

Do you know what is worse than all this? It is that one becomes habituated to it. (50.)

I will vomit upon my contemporaries the disgust with which they inspire me, even if I have to burst my breast to do it. (52.)

It seems to me I am traversing an endless solitude in order to go I do not know where. And I myself am the desert, the traveler, and the camel; all in one. (54.)

In the biographic clinics of private or of public patients, there is a constant repetition of the complaint of old age coming on prematurely, even in youth. Eyestrain suffering quickly etches in the face the indelible lines of the waste of life in conquering the insuperable and Sisyphian task. It is indeed an ever-recurrent and never-renounced Cadmean victory. In Flaubert's case, it, of course, began early. His "innocencies," "simplicities," etc., appeared in childhood, and his school days were miserable.

In my own eyes I seem immeasurably aged, older than an obelisk. (25.)

Alas, I am not as gay as formerly. I am growing old. I no longer have that magnificent *blague*, etc. (24.)

Ten years ago I was ruddy, all was perfume, and I exhaled life and love; now I see maturity near to withering. (25.)

For three days, although I work long (about ten hours a day), I am seized with an unparalleled sadness; I feel in my soul a mortal colic of bitterness. (25.)

Oh, how old I am growing, how old! (32.)

Sometimes I feel exhausted and tired to the marrow of my bones, and I think of death with longing as an end of all this anguish. (38.)

I have had hypochondria. Once at the height of my youthfulness I was thus seized for eighteen months, and I nearly succumbed. (38.)

I am submerged in a kind of black melancholy which appears with or without reason many times during the day. It passes and then it begins again. It is a long time since I have written. Nervous strength fails me. (49.)

As for myself, I am a used-up man; my brain will never again act normally. (49.)

His profound ennui, discouragement with everything, his wish for death, to be forever rid of his *moi*. (51.) (*Goncourts.*)

But I feel myself mortally wounded. To create a work of art one must not be burdened with care, and this is not true of myself. I am neither Christian nor Stoic. I shall soon be fifty-four years old, and at this time of life one does not change his habits or remake his life. The future has no good to offer me, and the past horrifies me. * * * Old age and decadence. As to literature, I do not believe any more in myself. I find myself empty—a discovery with little consolation in it. (54.)

I am seized with fits of prostration, when I feel as if annihilated or about to explode. (55.)

As for myself, I consider myself done for. My brain will not recover itself. One cannot write when one has lost one's self-esteem. I only ask for one thing, that is, to die and be quiet. (59.)

And this of a man of splendid natural health and endowment of vitality, normally exuberant, expansive, and life-loving. As in others, here, too, the depression and abnormality proceeds almost to insanity. At the age of 19 Mme. Lugier told the Goncourts that she feared he would lose his mind. There is a lurid suggestiveness in the story of Flaubert, told by himself, in reference to a poor, hysterical and weak-minded man who believed he had a tape-worm, and whose entire life and actions were dominated by the tyranny of this belief, so that it dictated his food, drink, his going and coming, etc. Flaubert was fascinated and ends the tale by, "I find it makes me giddy."

Louis Lambert of Balzac struck me like a thunderclap; it is the story of a man who became insane in thinking intangible things. This has stuck to me with a thousand hooks. (31.)

How close to insanity we sometimes feel ourselves, I especially. (31.)

After bordering on, "grazing" madness or suicide, I am now completely recovered. (49.)

In all the previous cases studied and in the vast majority of private patients suffering from eyestrain, the oculist finds an unconquerable driving and necessity of walking, journeying, hydropathizing, or some other form of eye-rest. In Flaubert's case there are illuminating and seemingly contradictory exceptions to the rule. But closely studied they not only "test," but they "prove" it. In the first place, Flaubert spent more time in travel and trips abroad than the "Monk of Croisset" is usually supposed to have done. There was the summer walking tour with Du Camp, and the two years' Oriental journeying; there was another trip to Africa, one to England, a coaching tour through several countries, many outings to Paris, etc. During these times there was a return of normality, happiness, gayety, while melancholy, pessimism, and ill health disappeared in an instant, and until the day of the return and resumption of literary labor. Then sickness and horror began. It is true that while at his work in his room he was seemingly the worst of hygienic sinners as regards exercise. But thereby hangs a tale! The beginning of the habit of staying in his room and not exercising was naturally and surely the shock and fear of having epileptic seizures while out-

side of the house. There was a reckless, ill-advised, but most determined resolve on that score. His mother had to torment him to make him walk in the garden. He never went beyond, he had no horse, no boat, etc. He would sit half a day in the same position. He worked at his literary task fourteen or fifteen hours every day, going to bed at 4 A. M., and often at it again as early as 9. This continued for some eighteen months. At the age of 32 he says he had not taken a walk or seen the country for two years. He finally came to contend that walking was hurtful to him or to anybody. He tried to "get even" with the still small voice by such outbursts as these:

Too much rowing, too much exercise! Yes, sir! The civilized man has not such a great need of locomotion as our friends, the doctors, insist. (57.)

I am now reading books on hygiene; how comical they are! What impertinence these physicians have! What asses, for the most part, they are! (53.)

I am reasonable. I go out every day. I take exercise and come back tired and even more stupid. This is what I get for it. (54.)

The overlooked solution of this sorry and puzzling contradiction is at hand: While at his work he walked, howled, stamped, declaimed, like a madman. Passers-by wondered and gossiped. This served a double purpose. It enabled him to get exercise of a sort, it is true, but real nevertheless, and it was his peculiar and logical method of whipping himself into excitement, "white heat," that is, of overcoming the inhibition of mental action due to his eyestrain.

My chamber walls remember still my frightful oaths, the stampings of my feet, and my cries of distress which I vented alone. (24.)

It is very late, and I am tired. My throat is raw from having yelled all the evening in writing, according to my exaggerated habit. (32.)

Let no one say that I take no exercise, for I carry on so that sometimes I walk several leagues a day in composing. (32.)

I howl! I sweat! It is glorious! It is sometimes decidedly more than delirium. (34.)

Howling from morning until evening almost to break my breast. (38.)

In the silence of my workroom I indulge in such howlings and fury that one would think it was a horse galloping, neighing, and kicking. (39.)

There is scarcely one eyestrain sufferer that is not a victim of insomnia. When the morbid reflexes are resisted by the brain, when one organ is not too persistently or violently harmed, when the struggle for health is obstinate, and its regaining has not become impossible, then sleep is possible and some measure of refreshment is usually secured. Flaubert's case again illustrates the clinical truth:

I have been two days without accomplishing anything and I am very tired, worked out, most sleepy. (31.)

For too many nights I have gone to bed late, rarely before three o'clock. It is a stupid way in which I exhaust myself, but I wished so much to be done with this novel. (32.)

I slept a good part of the afternoon, and took up my work again in the evening with great exhaustion. (32.)

I have the greatest need of sleep now for several days, and I prefer to lie completely fallow rather than half-work. (32.)

For two and one-half months my best night's sleep has been five hours. Finally, after three days, I slept my fill and am brutalized by it. (51.)

I sleep twelve hours a day; it rests my poor brain. (52.)

In the last eight days I have slept altogether ten hours. I keep up with cold water and coffee. (55.)

I have probably injured my brain severely, judging according to my sleep, because I sleep every night ten or twelve hours. Is it the beginning of softening? (56.)

That mysterious, protean, universal disease, called by the senseless name, "migraine," is surely 99 times out of 100 due to eyestrain, and just as certainly Flaubert was a lifelong sufferer from it. His naturally strong, and in all parts and organs equally strong, physique enabled his organismal wisdom to endure the assaults of the morbid reflexes upon each and every individual part with marvelous success. Only once, indeed, did one mechanism, the brain, fail to neutralize or cast off the ceaselessly incoming irritation or morbid reflex. But, thanks to its inherent vigor, and probably to opium, it was able to resist the epileptic storm, and the ship righted itself finally, and pursued its course. I shall briefly allude to some of the diseases which are now more or less well recognized as the results of eyestrain, the effects of the derouted reflexes, seeking a denied outlet for their excesses and morbidities of innervation.

It is remarkable how often eyestrain patients complain of ever-recurring colds, coryza, grippe, etc., and how free they become with proper glasses. I have one patient who gets a violent cold or coryza whenever his glasses are so ill-adjusted as to bring his astigmatic axis five degrees out of precision. Many such cases could be epitomized. Flaubert suggests a similar story.

My cold has perhaps purged my head, for I feel better. (32.)

For three days extremely stupefied with a violent coryza. (34.)

Grippe has seized me, of the most violent kind, with diseases of the stomach. (37.)

My grippe appears to be lightening. (46.)

Frightful colds and grippe, for six weeks. (52.)

An abominable attack of grippe. I cough, I blow my nose, I spit, I sneeze continuously, and I have fever at night. (53.)

"Rheumatism" and "neuralgia," etc., are frequently only meaningless names for eyestrain. At 26, Flaubert had "rheumatism" in the neck.

I write you with great difficulty, because since yesterday I have an attack of rheumatism which gets worse every hour. I suffer enormously and am most irritable. (31.)

My winter has been miserable. I have suffered from rheumatism and from violent neuralgia. (45.)

I was sick all last week; my throat was in a frightful condition. (51.)

I have had to have one of my last molars pulled out. Besides, I have lumbago, and moreover blepharitis. (57.)

Flaubert suffered frequently from boils and skin affections, and still more from "toothache," of which there are bitter complaints throughout much of his life. In private practice there are occasional examples demonstrating that the eyes are the causes of such affections.

Apparently that no organ should be exempt from the morbid reflex, the ears (as sometimes happens) became abnormally sensitive, and sometimes the hearing was so peracute as to become a real torment. Flaubert tells one of his correspondents that he has heard people speaking in a low voice through closed doors thirty yards away.

As was to be expected, there are few and unimportant complaints of the eyes themselves. Photographs show these to have remained exceptionally clear and healthy. There are a few complaints of styes, blepharitis, etc., and just before death he says that his "eyes begin to grow weary, for I have abused them more than ever." This is all in accord with recognized clinical experience. The more perfectly visual acuity and binocular vision are preserved, the more certainly the morbid reflex to the eyes is escaped, and the more certainly other organs must bear the brunt and the hurt. The more the complaints as to the eyes, the better the general health.

The irritability and sensitiveness resulting from all the unhygienic conditions, overwork, and disease, were natural and necessary. It is an old and daily-repeated story:

If having sensitive nerves were enough to make a poet, I should be a greater poet than Shakespeare, than Homer. (31.)

Mother came in at ten to say good-night, and I was so frightened that I shook with terror. * * * What a wretched machine is this body of ours, and all because a fellow was working at a phrase. (31.)

In order to write there must be the *impossibility* of being interrupted, even when I wish to be interrupted. (32.)

The bromide of potassium has calmed me. (54.)

Some writers and one of his physicians have charged Flaubert's excessive smoking as being the cause of some of his symptoms. He did smoke too much throughout his life. Once he speaks of having smoked fifteen pipes in one day. It is possible that his inflammation of the tongue in 1854 may have been caused by the habit. Flaubert did not believe in the theory.

In what vices I should indulge if I did not write! The pipe and the pen are the two safeguards of my morality, a virtue which is dissipated in smoke by the two tubes. (32.)

We cannot tell; we know nothing about the effects of small doses of tobacco (in chewing and smoking) habitually kept up for years. In an age when billions of money are expended in tobacco, the medical profession is, apparently, concerned not at all about this important drug-habit.

The two organs most commonly affected in eyestrain, the two almost constant symptoms of "migraine," are headache of some kind, and indigestion of any kind. As to headache, the "iron band about the head" is a symptom almost every day complained of in the oculist's office. Flaubert speaks of it, after writing twelve hours:

My mind is worse off—due to the leeches put on me yesterday, and which scratched my ears. (23.)

For several weeks I have had pain in my cerebellum so intense as to make me cry out, and Sunday the attacks began again. (32.)

Heavens! How my head aches! I must go to bed. My thumb is furrowed by the pen, and my neck wrenched! (32.)

Concerning the diseases of digestion, a great authority, a famous general physician, Professor Musser of Philadelphia, has lately publicly asked:

Who has not seen the correction of errors of refraction relieve so-called "bilious attacks," periodical vomiting, anorexia, indigestion, and other gastric symptoms? The cure of grave organic [should be *functional*] ocular defects relieves similar gastric conditions. The subject is familiar to all.

With proper reverence for Dr. Musser, it must be said that neither is the subject "familiar to all," nor is it scarcely ever acted upon. Every book on gastric and intestinal diseases, in the world, shows the utter, absolute and appalling unfamiliarity of "all," at least "all" the "experts." Poor Flaubert and all the rest of the Europeans could not suspect it, and at this present day they could not get a physician in all the continent to think of such an etiology nor of such a cure. This is how they suffered then, and still suffer:

After all, life is only a continual indigestion. (26.)

My viscera have been seen through my skin leaping and bounding. (31.)

All the evening I have had pain in my stomach and belly to make me faint if I were capable of fainting I think it is indigestion. I have also great headache; I am exhausted. (32.)

All this time I have been physically ill, with atrocious stomach troubles. I have had to go to bed with cramps in all my extremities, with pains in the back of my head. (38.)

[Back at Croisset.] I have suffered greatly this autumn: I have had frightful stomach disease. (38.)

When I wrote *Bovary* I had the taste of arsenic in my mouth so much, and was so poisoned myself, that I had two attacks of indigestion that I twice vomited up all my dinner. (47.)

One of his biographers adds that there is no exaggeration in this as when Flaubert gave way to his feelings he repeatedly became literally and physically sick at his stomach. A better observation would have noticed that it was not a powerful imagination in sympathy with his heroine that caused the stomachal malady, but that it was simply old-fashioned sick headache, "the disease whose nature is unknown" (Osler), but which is always due to eyestrain.*

When I am not hungry the only thing I am able to eat is dry bread. The most indigestible things, such as green apples and lard, lessen my stomachal distress. And so on. A man without common sense cannot live according to the rules of common sense. (48.)

Flaubert, like thousands of others suffering from "migraine," was struck by the quick recovery, and the equally quick return of the disease:

One thinks himself cured at times, and then awakes to find greater suffering than ever.

To epitomize: Flaubert from boyhood to the day of his death was the victim of unrecognized eyestrain. His epilepsy, typical or atypical, his "hysteroneurasthenia," his "migraine," or whatever name be given his symptoms, was the glaring consequence of abuse or overuse of slightly astigmatic or otherwise ametropic eyes. The mental and moral shock of the discovery led to the morbid seclusion, and unhygienic life, but every indication points to a control of epileptic tendency by means of opium. The character of his *Saint Anthony* (second style) and the Paris episode of morbid activity alternating with morbid slumber, corroborates this view. Denied creative ability, Flaubert's mind took refuge thereafter in the perfection of phrase and style, and a vast school of so-called literature, morbid in itself, and inartistic to death, sprang from the diseased example. Flaubert's success in this endeavor was self-confessedly a failure. The life of unhygiene, of systemic, and varied disease, was partly offset by the violent "exercise" he habitually took in his study, by means of howling, declaiming, stamping, walking, etc. The organismal wisdom thereby achieved three compensations: 1, ocular rest; 2, excitation of the emotions and mind to overcome the inhibition of eyestrain; 3, muscular exercise. The inhibition of normal cerebration due to his eyestrain is the second most striking fact both of his history and of his literary activity. For the rest, his diseases of the head and stomach, his colds, grippe, rheumatism, neuralgia, etc., were mostly and chiefly those now well recognized as exhibitions of "migraine," so-called, or more correctly called eyestrain. His pessimism was the inevitable result of eyestrain, plus the incidental conditions described.

Swift, Nietzsche, and Flaubert! None indulged in more reckless and unhygienic abuse of their bodies than these. They did not scorn their duties to this heroic friend and servant, they were utterly unconscious of duties to it; none more certainly outraged every common-sense rule of ocular hygiene; in none were the horrors of eyestrain more plainly manifest, in none its wrecking power on character, intellect, and will, more evident; and in none were the injustice and insults more patently avenged. And they were the world's arch pessimists and cynics, the three greatest haters of humanity which humanity can exhibit.

*How little Flaubert's stomach was an "irritable" or morbidly disposed organ is shown by the fact that in an eleven-day rough sea voyage he was not in the least seasick, but was the life of the whole company, full of joviality and wit.

SALINE BEVERAGES IN TYPHOID FEVER AND THEIR EFFECTS ON HEAT DISSIPATION.

By JOHN B. TODD, M.D.,
SYRACUSE, N. Y.

In typhoid fever the specific germ is first taken up by the intestinal lymphatics, and from these are carried by the lmph stream to the blood. The germ can be cultivated from the blood in a large percentage of cases before the Widal reaction can be obtained.[1] Coleman and Buxton[2] found in examinations made during the first week of the disease positive results were obtained in 93 per cent. They write: "It would appear from this that in typhoid fever the earliest and principal seat of infection is the blood, and that the disease may in truth be regarded as septicemia. If this be true, we may, in passing, call attention to the utter futility of attempting to control typhoid fever by the administration of intestinal antiseptics."

While the germs are distributed through the blood they have a tendency to congregate in the lymphatics and the intestinal lymphatics (Peyer's glands), which soon become impaired in their function by this invasion. Relating to this condition Thacher[3] writes: "The smaller lymph channels, more particularly in and around the nodules of lymphoid tissue, are especially sensitive to the infection. The tendency which typhoid bacilli show to lymphoid structures of the mucous membrane is not limited to the intestines; the intestinal lymphatics, by being also exposed to colon bacilli, may also become infected by them."[2]

The fact that the typhoid germ is taken up by the lymphatics and that the lymphatic system seems to be especially favorable to their multiplication, no doubt accounts for the want of leucocytosis in typhoid fever. Landois[4] says: "The leucocytes increase by division in part by mitosis, in part by amitosis, especially in their germ centers, that is, the lymphatic glands and adenoid tissues." Thus, when the lymph glands are invaded by the typhoid germ the leucocytes can no longer use these glands as germ centers, for multiplication and hypoleucocytosis is the result. While the leucocytes are diminished in the blood, there is an intense phagocytosis in the areas of infection, *i.e.* the lymph glands. This phagocytosis is most intense in those glands nearest the location of the primary infection, the small intestines, but occurs in diminished intensity in all lymphatic glands in direct proportion to their remoteness from the intestine—as spleen, liver, and heart.

The swelling of the lymph glands is due to the distention of the phagocytes with lymphoid and other cells which finally interferes with the capillary circulation: phagocytic degeneration occurs, fibrin is precipitated, and necrotic tissue is the result. This necrotic tissue may become resolved, or otherwise an ulcer is formed.

Mallory,[5] in conclusion of an exhaustive study, says: "These phagocytic cells are produced most abundantly along the line of absorption from the intestinal tract, both in the lymphatic apparatus and in the blood-vessels," and "that they are produced by the absorption of toxins eliminated from the blood-vessels. The necrosis of the intestinal lymphoid tissue is accidental in nature, and is caused by fibrinous thrombi, which owe their origin to degeneration of phagocytic cells beneath the lining endothelium of the vessels."

In treatment of typhoid fever there is universal agreement upon the value of milk diet, but in the further management there are three principal modes of practice. First, the various intestinal antiseptics, second, the plan of no medication, and, third, the plan of physiological elimination of bacteria and their toxins, and that of heat dissipation by saline beverages. To illustrate the three varieties of treatment, or better, management, I will briefly report seven cases:

Case I.—Mr. G., aged 51, admitted September 5; temperature 103.5°. Was given calomel and soda and put on a milk diet, 4 oz. every two and one-half hours and 15 minims chlorine water every four hours; broths were given as required. In twenty-one days he was convalescent. The average temperature for the time was 102.2° (the average temperature obtained from the maximum and minimum daily temperature) and the average urine was 25.76 oz.

Case II.—Mr. T. C., aged 25, admitted the third day of the disease with temperature of 104.1. He was given calomel and castor oil. Diet was 8 oz. of milk every four hours with lemonade and broth occasionally. Baths were given when the temperature was above 102.5. There was no medication. On the twenty-second day of the disease he was convalescent, average temperature was 100.97°, average urine, 35 oz.

Case III.—Mr. H., admitted the fifth day of the disease, with temperature 104°. This case was managed the same as number II, with no medication; the nineteenth day of the disease temperature was practically normal, and he was given soft egg and toast. There was a reinfection and temperature went up to 104° for three days; the original diet was resumed, and he was convalescent on the twenty-seventh day. The average urine, 39 oz., and temperature, 100.5°.

Case IV.—Mr. F., aged 27, had temperature of 103.4° on day of admission; was put on milk and lime water diet and given 15 minims chlorine water every four hours; after three days this was discontinued and he was given an antiseptic solution, 4 oz. every four hours; on the seventeenth day of admission he was convalescent, average temperature, 100.8°, average urine, 49.29 oz.

Case V.—Mr. F., aged 24, temperature on admission was 105°; his diet was two quarts of milk each day, and he was given two quarts of antiseptic solution per day. He was convalescent on the twenty-second day, average temperature, 102.25°, average urine, 77½ oz.

Case VI.—Mr. K. Temperature on admission, 103.8°; diet and treatment same as in Case V; convalescent on twenty-second day; average temperature, 101.3°; urine, 81 oz.

Case VII.—Mr. R., aged 36, had temperature of 104.8°; on first day was given castor oil and put on milk diet, two quarts per day, sponge bath several times a day; no medication, but was given three quarts of saline beverage per day. The following is the formula: Sodium chloride, 10 grains, potassium bicarbonate, 5 grains, in 8 ounces of water; add a teaspoonful of lemon juice; give every two hours. He also had 7½ grams of castor oil every four days. Castor oil is recognized as the best remedy in infantile diarrhea and cholera infantum; it cleans out the retained septic material, and is, in fact, a true intestinal antiseptic. Its use in conjunction with the saline beverages in typhoid fever keeps the mucous lining of the intestines clean and prevents the troublesome and exhausting diarrhea. After six days the evening temperature did not exceed 101° and the saline was reduced to five pints per day. The nineteenth day he was convalescent, the average temperature was 100.76°, and the average urine, 86.3 ounces. Tongue remained clean throughout the disease; no delirium and not much emaciation.

Case VIII.—Mr. H., aged 21, had temperature of 103.7° the first day. The case was managed the same as No. VI, and he was convalescent on the twenty-first day; average temperature, 101.5°. The nurse failed to accurately record the urine, tongue remained clean, and no unfavorable symptoms developed in the disease.*

In all these cases a positive Widal reaction was obtained, and in Cases II and III the germ was cultivated from the blood, and a positive diagnosis made several days before the Widal reaction could be obtained—in one case as early as the fourth day. At the first glance there does not seem to be much difference in these cases; they were all types of mild infection, or were rendered mild by their management.

A fever patient, with a temperature of 104.8° in a person weighing 140 pounds, has about 125,000 heat units in excess of the normal temperature. This represents Case No. VI, when the use of saline beverages was commenced. For the following three days the average temperature was 101.9° and the average daily urine, 97 ounces. In part this decline of temperature was due to washing out of the bacteria and their toxins. Simon,[1] in writing of the typhoid bacillus in the urine, says: "Often the bacilli are so numerous as to render cloudy a freshly voided specimen of urine;" and in part the decline was due to the germicidal power of the blood, being increased by the stimulating effect of the salines on the intestinal secretions,[6] and also in part it was due to *physiological* heat *dispersion* by diuresis, which in this instance amounted to 113,000 calories, each twenty-four hours.

In a normal person heat production is a continuous process estimated by Landois[7] at 100,000 calories per hour and exceeds heat dispersion; also a continuous process just enough to maintain the body at approximately 37° C. In febrile disease the bacteria and toxins act to increase heat production to a greater extent than dissipation, and an elevation of temperature results. In diabetes mellitus, on the other hand, heat dissipation by diuresis exceeds heat production and a subnormal temperature results. Tyson[8] mentions a lowering of 1 to 2½ degrees F. and Landois[7] states that a reduction of temperature below 86° has been observed in diabetes. This subnormal temperature is due in part to heat dissipation by diuresis. In cholera[9] also there is often a lowering of temperature from 1 to 10 degrees, due in part to the enormous discharge and vomit of rice water carrying the heat of the body with the serum. The following chart will show the relative heat dissipation in these cases:

Case No.	Days duration of disease	Average daily temperature C.	Average daily urine, ounces	Average daily heat dispersed in calories†	Treatment and diet
1	21	39.01	25.06	30324	Milk; chlorine water,
2	21	38.31	35	40531	Milk; no medication.
3	27	38.04	39	44845	Milk; no medication.
4	17	38.22	40.27	56944	Milk; chlorine water and antiseptic solution.
5	22	39.02	77.5	91410	Milk; antiseptic solution.
6	22	37.72	81	92357	Milk; antiseptic solution.
7	18	38.2	86.3	09651	Milk; saline beverage.

*For access to case records the writer wishes to acknowledge his indebtedness to Dr. H. E. Elsner of the Hospital of the Good Shepherd, Dr. J. L. Heffron of St. Joseph's Hospital in this city, and to Dr. C. L. Dana of Bellevue Hospital, New York.

†The heat unit, or calorie, is the amount of heat required to raise the temperature of 1 gram of water one degree; 1 fluid ounce of water weighs 29.5737 grains; on account of its salts 1 fluid ounce of urine sp. gr. 1012 would weigh 29.927 grains. The specific heat of urine would be greater than water. For want of definite information the writer assumed the specific heat of urine to be 101, which would give 30.228 grams calories in 1 ounce of urine. Thus, Case I, 25.76 ounces × 30.228 × 39.01 = 30.224 calories dissipated per day. The writer wishes to acknowledge his indebtedness to Dr. Albert P. Brubaker, professor of physiology and hygiene at Jefferson Medical College, Philadelphia, who has kindly gone over this work and who writes, "I have carefully gone over your method and calculations, and so far as I can see both are correct."

It would seem that the use of chemical substances like chlorine water are of slight value if not utterly futile, as Coleman and Buxton conclude,[2] when the blood is swarming with bacteria as early as the third and fourth day as has been observed by Dr. Buxton[1] and others.

We trust the evidence of the Widal reaction for the purpose of diagnosis without thinking that its action results from the fact that the blood has been swarming with typhoid bacteria for days, until the first crop—so to say—are dead and the agglutinins[2] therein contained are released into the blood stream as evidenced by the agglutination which we rely upon for positive diagnosis, and then we treat the case with antiseptics as one of local intestinal infection. Why is not one therapeutic belief in the facts of bacteriology as logical and strong as our confidence in it for the purpose of diagnosis?

Chlorine water is one of the most powerful oxidizers known and quickly combines with any organic substance, and to suppose that it will pass out of the stomach uncombined seems to be beyond the legitimate use of the imagination; experiments *in vitro* are hardly applicable to processes *in vitro*. The use of large quantities of acetozone water—one to two quarts per day—is of value in reducing the temperature by diuresis, at the same time washing out the toxins and bacteria, but the same amount of plain water would do as much. It is of doubtful value as an intestinal antiseptic. Its use is open to one great objection which overbalances any good that might come from its use. The diuresis produced soon exhausts the system of its salts, which are necessary to preserve the integrity of the blood plasma and for the function of leucocytes. The exhaustion of the salts from the blood tends to cardiac arrest, and, in a critical case, when the life nearly hangs in the balance, the little one way or the other will determine the result. A deficiency of inorganic salts will entail cardiac arrest, which would not occur if the blood had the required amount. This is well stated by Green[10] when he says, "Exhaustion as applied to the heart expresses states in which the inorganic salts necessary to the contraction of the heart are removed or disturbed." This criticism applies usually to Cases II and III, which were on an exclusive milk diet but no medication; the fatal defect is that the system is being exhausted of its salts and, as stated by Sajous,[6] are not replaced in the restricted diet. Hatcher and Sollman [11] made an exhaustive study of the so-called retention of chlorides in febrile diseases and demonstrated positively that it was salt starvation, and, recognizing this defect in a milk diet, they recommended the addition of fifteen grams of sodium chloride to the milk taken per day.

It is evident that the use of saline everages at the same time augmented the elimination of bacteria and toxins, also preserved the molecular constituents of the blood, and aided materially in reducing the temperature. A comparison of Cases I and VII illustrates this. In Case No. I the heat dissipation was only 30,324 calories per day, while in Case No.

VII treated with salines it was nearly 100,000 calories per day for the entire course of the disease.

Cases of excessively high temperature require sponge, or tub baths, but we should recollect that, as stated by Landois,[7] the secondary effect of cold baths is to stimulate heat production, and that a case of fever treated with cold baths shows a greater daily temperature variation, due, no doubt, to the secondary stimulating effect. Schafer[12] says that "the mean daily temperature and daily variations are very slightly or not at all affected by baths."

The saline beverages preserve the germicidal powers of the blood by acting upon the albuminates of the serum according to Buchner[13] or by increasing the alkalinity of the blood as Von Fodor[13] demonstrated, and in that measure increasing the activity of the white corpuscles. Vaughan and Novy[13] say, "It has been shown, beyond controversy, the blood serum owes its germicidal properties to the white corpuscles," but Sajous[6] has pointed out that it is a trypsin-like substance taken up by the white cells.

However, if there be a lack of agreement as to the identity of the germicidal powers of the blood, there is unanimity in the opinion of the necessity of the alkaline salts in the blood for its efficacy, and any treatment of febrile disease is defective if due regard is not paid to maintaining the alkalinity of the blood. Not only is leucocytic formation prevented in their germ centers, the lymph glands, but, according to the exhaustive study of Mallory,[5] they are actually destroyed by the phagocytic endothelium cells; these phagocytic cells take up and digest lymph cells, red blood cells, and everything that has become contaminated with typhoid toxin.

They are the defense of the system, for their activity and vigilance intercepts all sorts of intestinal bacteria and toxins that would otherwise find entrance into the blood through the lymph channels. In typhoid, the lymph cells evidently become saturated with toxins, and to destroy the toxin the cell must be destroyed, as we blow up a building to check a conflagration. In this fierce fight the physiological function of lymph glands, that of taking up and supplying the products of digestion for the use of the system is impaired or arrested, so that the patient lives off his own flesh.

The real defensive fight is during the *first week* of the disease; if the infection is of a mild character the phagocytic cells are able to digest and destroy the toxins without material injury to the lymph glands; and, on the other hand, if the infection is severe and effects of the phagocytic activity exhaust the salts and fluids of the body, upon which their functional life and activity depend, they become weakened, undergo degeneration, and fibrin is precipitated. This occludes the circulation and a necrotic center is formed; these foci may undergo resolution, or, in more severe cases, it may slough off and form an ulcer. In this connection we may note the effect of typhoid germs and toxin upon the motor cells of the spinal cord. Nichols[14] found extensive cell degeneration in a case that was fatal on the eleventh day. The degeneration changes found were similar to those produced by arsenic, strychnine, alcohol, etc.; he says: "No doubt in our typhoid cases, too, they may be attributed to the direct action of the typhoid toxin."

From a consideration of all of these facts which constitute the pathology of typhoid fever it is evident that the lymphatic system should receive our earliest attention in this disease. It is the phagocytic activity upon which depends the result. If a proper amount of fluids and alkaline salts are provided in the *earliest stage* of the disease their efforts are helpful, and, on the contrary, if these are withheld, then the efforts of the protective forces of the body are hampered, and the chances for an unfavorable issue in the case are increased.

The need and value of the *early* use of salines *in all febrile diseases* to preserve the antitoxic properties of the blood and cells was first pointed out by Sajous.[6] "Why not," says this investigator, "supply the system from the onset of a febrile disease, or, indeed, any other general disorder, with the constituents than preserve the mechanical freedom of all nutritional and protective functions, including those of the adrenal system itself?"

Following the publication of Vol. I of Sajous' "Internal Secretions," in 1903, the writer was impressed with the importance of the early and continuous use of salines in all febrile diseases, but could see no reason or justification for giving the fluid by hypodermoclysis, as had been done in pneumonia by F. P. Henry[15] or by enema. The first method is too surgical, and, besides, the system needs a continual supply, while the forcing into the tissues of 8 or 16 ounces at one time is not a physiological process to say the least. To use the solution by enema is to promote the absorption of intestinal bacteria and toxins. As stated by Landois,[4] "Sodium chloride solution is better absorbed than water," and "from the stomach are absorbed aqueous salt solutions within six minutes."

Believing the stomach to be the physiological organ fitted to absorb fluids according to the wants of the system, the writer began giving saline beverages, first in pneumonia,[16] afterwards using it in scarlet fever and in typhoid fever. The writer does not claim that this method of using saline beverages is the best treatment for very desperate cases, but if saline beverages are used *from the inception of the disease*, as emphasized by Sajous, the number of desperate cases will be very materially decreased. The demand of the system for a continuous supply of salines is imperative. Landois[4] states that an adult in moderate exercise consumes 32 grams of inorganic compounds (salts) per day, and Hatcher and Sollman state that a person on a milk diet should have 15 grams of salt; so that if the writer has erred it is in not using enough, for in taking, 10 grains of sodium chloride and 5 grains of potassium bicarbonate twelve times a day would only amount to about 15 grams in twenty-four hours.

In giving the saline beverages, 10 grains of sodium chloride and 5 grains of potassium bicarbonate are added to 8 ounces of water; a teaspoonful of lemon juice is added, which produces a mild effervescence and which renders the drink very palatable, so that it is gratefully taken. There is about two-thirds of a grain of free citric acid in each dose, which gives it a pleasant tartness and adds to its palatability.

The absolute need of the system for water need hardly be mentioned when we consider that entire life processes are enacted in the various body fluids, and also that heat dissipation is almost entirely accomplished by the elimination of water, through the lungs, skin, and by urine. In febrile diseases the demand for water is augmented by reason of the increased respiration as well as by the increased metabolism throughout the system, and, if not supplied in abundance, heat dissipation is lessened, cellular life hampered, and the toxins retained: the fibrin is more readily precipitated in the lymph glands to form a focus for necrosis.

There can be no objection to any additional treatment deemed necessary in conjunction with the use of saline beverages, and the writer urges the pro-

fession to give their use a trial in febrile diseases and to report their results, and at the same time to make records of heat dissipation by the urine, that we may accumulate facts regarding it in different diseases, for it is evident that we have neglected to observe this physiological phenomena as a factor in many diseases.

THE DIAGNOSIS OF SURGICAL DISEASES OF THE KIDNEY.*

By ALBERT A. BERG, M.D.,
NEW YORK.
ADJUNCT SURGEON TO MT. SINAI HOSPITAL.

The task of making a diagnosis usually rests upon the shoulders of the general practitioner. Difficult and onerous as the problem often is, it is, nevertheless, one that he gladly accepts, for its solution imparts interest to his routine work and affords him the basis of a rational method of therapeusis.

The recognition of those disease processes which are surgical in character is especially hard in their initial periods; in their fully developed stages, when all the classical symptoms have developed, the diagnosis is much simpler, but at such times the aid that can be afforded to the patient is materially curtailed and lessened. Close clinical observation, exploratory incision, experimental research, and laboratory study have enabled us to interpret the manifestations of these affections much earlier, and to apply our therapy more speedily and with more success.

Especially is this true of the surgical diseases of the kidney. With the accurate methods at our disposal for the examination of these organs and their secretion we are able to ascertain, not only whether they are healthy or diseased, but also, in most cases, the exact nature of the malady which is present; and, further, we are in a position to find out whether one or both organs are affected, and, if the latter is the case, which is the more extensively involved, and finally we can determine what the combined and individual functionating capacity of the two organs is.

To a consideration of these several facts this paper is to be devoted, my aim being to present to you the subjects of the diagnosis of kidney disease and the determination of kidney function in their modern conception, so that you should be ready and able to interpret the clinical phenomena which diseases of these organs present in their early stages and to use them as a guide for your counsel to the patient.

*Read before the Eastern Medical Society, January 12, 1906.

The health or disease of the kidneys is determined from a study of the anamnesis, from physical examination, from urinary analysis, from the appearance of the ureteral mouths as seen with the cystoscope and from *x*-ray examination. The question as to whether one or both organs are diseased is positively answered by examination of the urine, drawn from each kidney by means of the ureteral catheter; and the functionating capacity of the two organs is ascertained from the total amount of urea which is eliminated in the twenty-four hours, and from the cryoscopic index of the blood and urine, while that of the individual kidneys is determined from the percentage of urea in the separated urines, from the cryoscopic index of the individual urines, and from a comparison of the rapidity and amount of chromogen and sugar which each kidney eliminates after a hypodermic injection of methelene blue and phlorizin respectively.

The Anamnesis.—The importance and aid of a complete clinical history in making a diagnosis is not appreciated by all practitioners. Their manifold duties often forbid them from devoting the time that is necessary for extracting from the patient a detailed history of his complaint, and yet it is safe to say that without this no correct diagnosis can be made in the majority of cases. A great many practitioners rely upon their examination of the urine and upon the presence of an enlarged kidney for establishing a diagnosis of surgical disease of these organs, and this, in spite of the well-known facts that even with well-advanced renal diseases there may be nothing abnormal in the urine and no palpable tumor or swelling of the kidneys. If an early diagnosis of renal affection is to be made, all the data which it is possible to collect must be made use of, and among these the facts which are to be elicited in a carefully taken clinical history are of the utmost importance.

Most patients with surgical diseases of the kidneys suffer with disturbances, in the frequency of urination, or from abnormalities in the gross appearance and in the quantity of urine which is passed in the twenty-four hours; hence, in taking their clinical history it is essential to ascertain how often they have to urinate during the day and night, what the urine looks like, *i.e.* whether it is purulent or cloudy or bloody, and whether the pus or blood is uniformly distributed in the urine, or whether it is present only in the first or last urines, and, if bloody, whether the blood is bright red or smoky in color. All these details are of the utmost importance for diagnosis. Thus the only evidence of renal tuberculosis in its early stages may be frequent, painful micturition and cloudy urine. Again, pus or blood, which is present only in the first urine that is passed, is never renal in origin; from this source these abnormal constituents are always distributed uniformly in the urine; and again smoky urine is believed by Gomprecht to indicate the kidney as the source of the blood.

But while, as stated above, most patients have these urinary disturbances early in the course of their maladies, yet it is not at all infrequent to see those who have been afflicted with renal disorders for a long time, without having observed anything abnormal in the act of urination or in the urine. As only the intelligent are accustomed to watch the gross appearances of their urine, it is easy to understand how it is that even considerable grades of pyuria and hematuria pass unnoticed unless pain or frequency of urination direct attention to the urinary organs and their secretion. How often do we find the painless hematuria which accompanies

chronic granular nephritis, malignant disease of the kidneys, aseptic renal calculus, and some forms of renal tuberculosis pass entirely unnoticed by the patient! Such individuals often seek our advice for disturbances of their general health, such as anemia, gastric or intestinal disorders, and their thorough physical examination then reveals the existence of renal disease.

The family and personal history of the individual also afford data that are of value for the diagnosis of the nature and causation of the kidney affection. Thus the age of the patient, the duration of the symptoms, and the rapidity of their development are important points to consider in determining the character of the renal malady, for malignant tumors of the kidney occur with greatest frequency at the two extremes of life, *i.e.* in childhood and infancy, and in advanced years; tuberculosis is especially common in young adults; hypernephromata develop gradually, whereas cancer and sarcoma progress rapidly. A history of family or personal tuberculosis, of a previous gonorrhea or syphilis, of trauma to or operation upon the urinary organs, of past or present affliction with other acute or chronic diseases, such as infections, pyemia, eruptive diseases, hemophilia, or, in women, of pelvic inflammation, pregnancy and child-bearing, also furnish a strong suggestion as to the particular character and causation of the kidney disease. I remember three patients with large suppurating infarctions of the kidney following small, comparatively insignificant suppurations of the fingers and toes, and a recent case of perinephritic abscess secondary to a carbuncle of the neck.

I therefore make it an invariable rule to ask about and look for abrasions and suppurations of other parts of the body when I have to do with pyogenic affections of the kidney, and conversely I keep the kidneys constantly in mind when there are febrile movements accompanying these conditions that cannot be accounted for in other ways. I need only mention the frequency with which renal tuberculosis is secondary to tuberculosis of the lungs and other organs, the oft occurrence of pyelitis and pyelonephritis with pregnancy and child-bearing, of acute miliary abscesses of the kidney after trauma to and operations upon the urinary organs, to indicate how important it is to elicit all the details of the previous history in making a diagnosis of the nature and cause of a renal affection.

We must not expect, however, to be able to make a diagnosis from the data which the clinical history affords. This always rests upon the facts which we ascertain from examination of the patient and his urine. It would be carrying coals to Newcastle were I to enter here into a discussion of the methods of physical examination of the kidneys and urine. I may be permitted, however, to remind you that the kidneys are retroperitoneal organs, and consequently have no respiratory mobility, that they have a definite shape, that they occupy the loin, or can be replaced into the loin, and after replacement will maintain their position in the loin as long as the individual is recumbent, and that the colon lies in front and to their inner side. These characteristics, especially the colonic relations, are important in the differentiations of kidney tumors from neoplasms and swellings of other organs in the abdomen, and they should be determined in every abdominal tumor which occupies the kidney region. As has been just stated, the colon lies on either side, in front of and internal to the kidney, the ascending colon passing across the right one from below and to the right upward and to the left, and the descending colon crossing the left kidney from above and to the left, downward and to the right. The position of the colon is most readily determined after it has been distended. This is best done by inserting a rectal tube 10 to 12 inches into the lower bowel, and then either pumping air through it into the colon with the bulb of a Davidson syringe, or forcing CO_2 gas into it from the nozzle of an inverted bottle full of carbonated water.

The importance of careful urinary examination in the diagnosis of these diseases cannot be too forcibly stated. It is essential that we should know the total quantity of urine that is passed in twenty-four hours, its reaction, color, and specific gravity; whether it is clear or contains a sediment, and, if the latter, of what this is composed; whether the filtered urine contains albumen or sugar, and what its percentage of urea is; whether it contains crystals of uric acid, oxalate, triple phosphates, leucin or tyrosin, pus or red blood cells, casts, epithelial cells or microorganisms, especially tubercle bacilli streptococci, staphylococci, or colon bacilli. I cannot dwell too strongly upon the importance of examining the urine for the presence of microorganisms, and especially since it has been proposed and become the practice of many to treat in a surgical way these forms of chronic nephritis that are commonly classed as Bright's disease. We know that some varieties of chronic parenchymatous and interstitial nephritis are due to the pathogenic action of virulent bacteria, *e. g.* streptococci, staphylococci, and colon bacilli, which the kidneys strive to eliminate from the blood in conditions of systemic infection with these organisms. These varieties of chronic nephritis cannot be distinguished either clinically or histologically from the chronic nephritis due to other causes, and experience has already taught us that this class of cases are especially likely to be favorably influenced by decortication and nephrotomy. It is thus apparent to you that to help us to select the cases of chronic nephritis that are fit for surgical interference and also to aid us in making the prognosis, the bacteriological examination of the urine is a matter of the very greatest importance. It goes without saying that this examination demands that the urine be drawn by aseptic catheter after thorough cleansing of the meatus urinarius and anterior urethra, or by aseptic ureteral catheters from the individual kidneys.

It is hardly to be expected that the practitioner will himself have the time or the inclination or the requisite training to properly perform the tests and carry out the examination I have just briefly outlined. We are fortunate, in this large city, of having at our disposal several excellent laboratories where the work can be and is thoroughly well done. It is necessary, however, that you should indicate what you desire the examiner to specially look for, and it is also important to remember that only positive findings have a real diagnostic value; negative ones mean nothing unless confirmed by repeated and repeated examinations.

The clinical history and a careful urinary analysis will usually enable us to diagnosticate the presence and probable nature of a surgical renal affection; but they do not help us to ascertain which is the diseased kidney or whether one or both organs are affected. To answer these questions we have to rely on the signs afforded by physical and cystoscopic examination and on the evidence afforded by analysis of the urine drawn from each kidney by ureteral catheter.

If the diseased organ is palpably enlarged, then physical examination will at once enable us to de-

termine the site of the affection. It is an error to think, however, that every diseased kidney is enlarged, or that every enlargement of these organs can be palpated. The organs may be extensively diseased and yet not at all enlarged, and if they are situated high up under the last two ribs they may be considerably enlarged and yet not palpably so. It is important to remember, therefore, that while a palpable enlargement of the kidney is an indication of its disease, an absence of this is no evidence either of the health or disease of the organ.

Pain and tenderness of the kidney to palpation are often relied upon to decide which organ is diseased. These symptoms, however, are very misleading. Thus it is well known to every surgeon that in many instances the diseased kidney is never painful or tender, while its fellow organ, either because of the extra work which is placed upon it by the affection of the other kidney, or because of a urotoxic degeneration of its parenchyma which is induced by the disease of the other kidney, occasions considerable pain and annoyance. These signs are therefore never to be looked upon as positive evidence of the disease of these organs; they are simply suggestive and are to be considered in the light of confirmatory evidence of those signs of disease which are to be obtained by cystoscopic examination and ureteral catheterization.

It is to be regretted that these last-mentioned means of diagnosis of renal diseases are not employed as frequently as their worth demands. A great many practitioners still regard the cystoscope and ureteral catheter as pretty toys that give no information of the kidneys that is really of practical or material value, and, unfortunately, a great many surgeons think that the data which are to be obtained by the use of these instruments can be replaced by these which are arrived at by simpler methods of examination. Others, again, believe in the value of these methods of examination, but hesitate to employ them because of the danger of carrying infection to the urinary organs which their use exposes to. In answer to the first objection, the writer wishes to say that the experimental stage of the cystoscope and ureteral catheter has long since passed; to the second, that the facts that are to be gained by cystoscopy and ureteral catheterization cannot be obtained in any other way; and to the third, that aseptic methods of examination will protect the patient from the dangers of infection, and that care in the performance of ureteral catheterization will shield him from an infection in the bladder extending upward to the kidneys. At all events, the writer has had several hundred cases of cystoscopy and ureteral catheterization done in all sorts of diseases of the kidney and bladder, and thus far has not experienced a single instance of infection of the bladder or kidneys resulting from the use of the cystoscope or ureteral catheter. This is owing to the fact that thorough asepsis is observed, and that care is taken never to permit the ureteral catheter to scrape along the bladder wall before it enters the ureter, and to avoid all traumatism to the bladder or ureter.

So valuable and important are the data gained by cystoscopic examination and ureteral catheterization with the analysis of the separately drawn urines, that the writer believes no one is entitled at the present time to undertake the treatment of surgical diseases of the kidney unless he is prepared to make use of them.

It is not necessary here to describe the methods of performing cystoscopy and ureteral catheterization, nor is it essential to discuss the relative value of the different cystoscopes that are on the market to-day. These details are for the experts in cystoscopy and ureteral catheterization, and it is needless to say that such an one should be proficient in the manipulation of all the models that are in general use at the present time.

I wish to-night to state briefly the information that is obtained by cystoscopic examination and ureteral catheterization of the condition of the kidneys and their functionating capacity.

In performing cystoscopy for diagnosis of the health or disease of the kidneys, we are concerned in the appearance and position of the ureteral orifice, and in the condition of the vesical mucosa. The normal ureteral orifice is a faint flesh-colored slit or rounded hole, and lies in the lateral angle of the trigonum on a slightly elevated ridge. The margins of the orifice are sharply and clearly cut. From it there appears at more or less frequent intervals depending on the secretory activity of the kidney an efflux of clear fluid that resembles a wave of glycerin passing inward across the trigonum, and accompanying this efflux there is a distinct peristaltic wave of the ureteral orifice. Changes in the shape, size, contour, and position of the ureteral orifice, in the character of the efflux and in the intensity of the peristaltic wave are frequently amongst the earliest signs of renal disease, and often throw considerable light upon the character and extent of the kidney affection. In general terms we may say that the changes in shape, size, appearance, and position of the ureteral orifice corresponds to and indicates the changes of the renal pelvis and ureter. Thus atonic *dilatation of the kidney, pelvis,* and *ureter* is attended by similar dilatation of the ureteric orifice, which assumes an elongated and furrowed or golf-hole shape.

Pyelitis with acid urine is attended with some dilatation of the ureteral orifice; the efflux is turbid and the peristaltic wave may be increased in force and frequency; whereas in *pyelitis with alkaline urine* the ureteral orifice is somewhat dilated, its lips everted, and the seat of scald like erosions and surrounded by congested mucous membrane; the efflux is muddy. In the late stages of such a pyelitis the ureteral orifice is warped and contracted.

As the kidney, pelvis, and ureter are not much altered in the painless forms of hematuria dependent upon chronic granular nephritis, malignant tumor of the kidney, aseptic renal stone, and some of the cases of renal tuberculosis, the ureteral orifice in these affections does not show any constant or marked change. If the pelvis is dilated, the ureteral orifice is similarly enlarged and is elongated and furrowed or golf holed. The efflux is bloody, the amount of the blood depending altogether upon the severity of the renal bleeding.

In renal tuberculosis the appearance of the ureteral orifice varies. In the early stages of the malady, before the tuberculous foci have commenced to break down, and before the pelvis has become inflamed, there are no changes in the aspect of the ureteral orifice or in the efflux therefrom. With the breaking down of the caseous areas, however, the pelvis of the kidney becomes inflamed and dilated and the ureteral orifice correspondingly becomes elongated and furrowed or golf holed, and the discharge of the caseous material in the urine causes the efflux from the ureter to be cloudy. As the kidney pelvis becomes more and more involved in the tuberculous process, and as the softening and breaking down of the tuberculous tissue proceeds with the consequent discharge of pus and tubercle bacilli in the urine, the changes in the ureteral orifice become more and more marked and

characteristic. The mucous membrane surrounding the orifice becoms reddened and somewhat edematous, and on it a few sparsely scattered tubercles, and not infrequently one or more sharply cut, sloughing ulcers, are to be seen. The rest of the vesical mucosa may afford further evidences of the disease in the shape of red, extravasated areas with white necrotic flakes on them, or superficial erosions or worm-eaten ulcerations.

If the tuberculous pyelitis is very acute in its development, the ureteral orifice appears thickened, irregular, and choked or very edematous. In the late stages of the disease, when the pelvis and ureter are considerably thickened and ulcerated and the seat of marked tuberculous changes, the ureteral orifice and the corresponding part of the bladder wall are dragged out of their normal position and ulcerated, the opening is patulous and irregular and the efflux therefrom is a puriform trickle or pure pus. The rest of the vesical mucosa presnts ulcerations and extravasations.

These ureteral orificial changes are very characteristic and are the earliest positive evidences of renal tuberculosis. As Baumgarten and his pupils have almost conclusively shown that urinary tuberculosis is primary in the kidneys and descends from these organs to the other parts of the urinary tract, it is essential if we wish to radically cure our patients of this malady to detect its presence as soon as is possible and extirpate the affected organ.

As has been stated in another part of this paper, frequent and painful urination and inconstantly cloudy urine, and in some instances a painless hematuria are the very first indications of tuberculous disease of the kidney. Patients with these symptoms, and especially women in whom there is no gonorrhea, and no infection of the bladder from other causes such as instrumentation, trauma, etc., should be looked upon with great suspicion as being affected with renal tuberculosis, and should be repeatedly cystoscoped in order to detect the very first positive evidences of the disease in the changed appearance of the ureteral orifice. Repeated search for tubercle bacilli in the urine should also be made, several quarts of urine being sedimented or centrifuged for this purpose. Not only is the cystoscope of great value in these cases for making the diagnosis, but in the absence of kidney enlargement it is the only means we have for ascertaining which organ is the diseased one.

In renal stone the orificial appearances of the ureter are not at all characteristic. If the calculus is located in the kidney parenchyma or in its pelvis, and there is no pyelitis present, there is no change in the ureteral mouth. If there is a pyelitis with alkaline urine, the ureteral orifice looks congested and scalded, its lips are everted, and the whole trigonum is reddened and swollen, the efflux being cloudy and somewhat more forcible. When a calculus passes through the lower third of the ureter and nears the vesical end there may be punctate extravasations in the immediate neighborhood of the orifice and the corresponding side of the interureteric bar may be thick and swollen. As the stone approaches near the bladder the extravasations become more numerous, until finally the orifice and its immediate surroundings become uniformly red and appear to be bruised. Sometimes there is considerable edema. If the stone is arrested in the lower third of the ureter, the mucous membrane of the orifice is protruded and everted, sometimes roughened and again irregular. The efflux may be normal. If the stone is impacted in the vesical end of the ureter and protrudes into the bladder it is to be distinctly seen.

With renal neoplasm the ureteral orifice does not appear altered unless the pelvis is dilated, when the opening is furrowed and elongated or golf-holed.

In three cases of *ureteral stricture* I have not found any changes in the ureteral orifice.

The *character* of the *efflux* and the *peristaltic wave* character of the efflux and the peristaltic wave afford us valuable data as to the condition of the kidney. A too forcible or too frequently repeated efflux points to increased work on the part of the organ or irritation of the ureter, *e.g.* by a calculus or blood clot or plug or mucus and pus. A cloudy efflux points to pyelitis, a purulent trickle indicates a crippled, suppurating kidney, and a solid pus efflux means secretory death of the corresponding organ. A blood trickle points to a crippled kidney or to moderate hemorrhage with diminished secretion of urine by the affected organ, while a solid blood efflux denotes a profuse renal hemorrhage.

After a thorough study of the ureteral orifice and vesical mucosa, the writer is accustomed in every case of supposed renal disease to catheterize both ureters, introducing the catheters up to the renal pelvis. Some experts doubt the advisability of this latter procedure in suppurating conditions of the kidneys or bladder, on account of the danger of infecting the kidneys, but the writer is of the opinion that aseptic methods of technique and care in the introduction of the catheters will render such danger a very remote one; at all events, in his many cases no infection of the kidneys has been occasioned in this way.

The introduction of the catheter is of the utmost importance, for only in this way can we demonstrate the existence of a ureteral stricture, the symptoms of which resemble very much those which are occasioned by renal calculus or renal tuberculosis. Furthermore, it is the only means we have for determining the exact anatomical location of an impacted ureteral calculus, and lastly, but by far the most important of all, it enables us to draw the urine separately from each kidney and thus ascertain the health or disease of the latter and also its functionating capacity.

TURBINECTOMY.

By E. HARRISON GRIFFIN, M.D.,

NEW YORK.

LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE nasal chamber is divided into two parts by the septum, forming the right and left nasal cavity. The right chamber is naturally slightly larger than the left. On the outer side of each chamber are found the turbinated bones or bodies, three in number and in some cases four.

The inferior turbinated bone is the most developed and the most compact in structure and is the only one which is an independent bone. It varies in length from twenty-five to fifty millimeters and in breadth from five to fifteen millimeters. The turbinated bones divide each nasal cavity into three divisions or meatuses. The superior meatus communicates by means of a foramen with the posterior ethmoidal cells. The middle meatus, situated between the middle and inferior bones, communicates with the anterior ethmoidal cells and through the hiatus similunaris with the infundibulum, which communicates at its upper and anterior part with the frontal cells and at its lower and posterior part by the ostium maxillare with the antrum of Highmore. The orifice of the lacrymal duct is situated at the anterior part of the inferior meatus. In the nor-

mal nose these meatuses are well defined and large enough to serve their purpose, namely, of providing drainage. If these meatuses are impinged upon by some foreign growth, a bead, a bean, or a shoe button, there is a pressure and the character of the normal discharge is very much changed. The opening of the anterior and the posterior ethmoidal cells, the antrum and the lacrymal duct into each side of the nose, brings this organ prominently to the front as one of the chief drains or sewers of the body. A fact often lost track of on account of its other functions, namely those serving as a breathing channel and as the organ of smell.

A space should always exist in a normal nose between the turbinated bones and the septum. This space should be much larger between the inferior turbinated and the septum, than the space higher up. If this space is occluded by the inferior turbinated bone encroaching or impinging upon the septum, the case is one of hypertrophy of the turbinated body. The posterior portion of the inferior turbinated body is very rich in blood-vessels and in some cases, a hemorrhage from one of these vessels is liable to occur under moments of excitement. I had one patient, a man who would have a hemorrhage from his nose every time he cohabited. During study or in a sedentary life, these blood-vessels are apt to swell and produce complete stenosis of the nose, while if the nose is examined after a brisk walk, the normal lumen of the nasal cavity is restored. I saw this excellently illustrated in a medical student, who applied to me some years ago for stenosis of his nose. When he called at my office, I found the septoturbinated space large enough for nasal breathing. I tried each nostril separately and found that he could breathe freely through both the right and the left. He stated that after he had been confined to the house for a few hours, his nasal space would close and he would be compelled to breathe through his mouth. I tried every manner of procedure in this case, but the only remedy that gave him any relief was an operation on his inferior turbinated bone, and since then he has been entirely free from his old trouble of stenosis and bronchial attacks in the winter. I have found this hypertrophy of the turbinated bone more common in the cases in which the patient has led a sedentary life and in which the laws of nature in regard to fresh air in the bedroom have been neglected.

The discovery of cocaine by Koller did more for the specialty of the throat and nose than for any other branch of surgery, not only by its anesthetic effect on the mucous membrane, but also by its power of contracting the blood vessels and enabling the specialist to search every recess of this chamber. The discovery of the action of suprarenal extract on the mucous membrane, also helped, for this agent has the same effect on the blood-vessels as cocaine, namely the power of contracting, but not the anesthetic effect of the former.

The characteristics of a normal nose are, a straight septum dividing the nasal chamber into two cavities about equal in space, the right being a trifle the larger, a small space between each turbinated bone, or in other words the meatus well defined and a space between the turbinated bones and the septum large enough to act as a drain for the various sinuses that empty into this cavity, and to serve for the free ingress and egress of air to and from the lungs. If a two per cent. solution of cocaine be sprayed into the nostril and ten minutes allowed to elapse, the mucous membrane covering the turbinated bones will be found drawn tightly over them and a perfect skeleton of the anatomy is opened up to view. If the inferior turbinated bone now encroaches or presses upon the septum, we have a case of hypertrophy of the bone itself. This hypertrophy can be overcome by only one way, and that is an operation. The spray of an astringent solution will give a certain amount of relief to the patient, but when the medication has been suspended, the old symptoms will return. The cautery is useless and is apt to do great damage in these cases, in which the bone itself is enlarged. Its application will not reduce the bony enlargement, but in applying it the septum is liable to be touched at the same time and the result is an adhesion of the turbinate and the septum, producing a complete stenosis of the nostril. These are tedious cases to treat and will call into play all the time and ingenuity of the surgeon to correct the deformity. I have just finished operating upon a case of this nature, in which the patient had been operated upon seven times by different surgeons and then applied to me for treatment. He had complete stenosis of one nasal passage, produced by the uniting of the turbinate with the septum.

The snare is serviceable in cases of pedunculated growths such as polypi, enlargement of the middle or superior turbinated, or in the ragged enlargement of the inferior turbinated body, known as the grub worm appearance, but useless in hypertrophy of the inferior turbinated bone itself. The operation of removing the inferior turbinated bone is sometimes done by means of director and scissors with Carmalt Jones spokeshave or with Stipanitis chisel. If the director and scissors are used the director is first passed under the inferior turbinal, the probe end of the scissors slide along the director and the mucous membrane and the bone cut through. If the spokeshave is used, it should be passed along the inferior meatus and the ring knife fixed well behind the projecting posterior end of the inferior turbinal and then by a sharp pull made to cut its way forward through the bone. I have never used these methods as they seem to me too rough and unsurgical. Dr. Stipanitis removes the bone with a chisel. The chisel is applied to the anterior end, and with the aid of a mallet is made to cut its way through the bone and overlying tissue. In criticising these methods, I would be led to believe that a nose that was large enough in its interior to admit the passage of either a spokeshave or a chisel would be large enough for a patient to breathe through. I have operated upon cases in which the inferior turbinated bone was so jammed toward the septum and the nose so blocked up that I had difficulty in introducing even the smallest, thinnest probe in my possession, and after the operation was completed I had difficulty in removing the mass, that I had amputated on account of the part being so firmly packed in the nostril, even after it had been thoroughly severed.

I do not believe in complete turbinectomy; only so much of the bone should be removed as is necessary to restore the normal canal and to give back to nature the proper function of the nose. A complete turbinectomy is much easier than a partial turbinectomy. In the latter, judgment is required as to how much should be removed, the cut is longer, as it is through the center of the bone, and the parts need trimming. If the operation of partial turbinectomy as been properly performed, six weeks after the operation, an examination will fail to show any marks of a surgical procedure and

the only result patent is a normal nose and the proper amount of breathing space and a canal for drainage. The great objection to complete turbinectomy is that it makes the passage too large and removes something that belongs there and has a function to perform. Partial turbinectomy only restores the normal anatomy.

From a polypus or other growth or a deflected septum an enlarged turbinal may be diagnosed by the fact that it retains the general outline of the normal turbinated bone and in its locality. A polypus is generally attached to the middle turbinated bone and is markedly pedunculated; a deflected septum would have its origin from the center of the nose. A patient with this deformity may apply with any of the symptoms that are secondary to nasal stenosis.

If the patient is an actor or a singer, he will find his head tones very much impaired and will complain of attacks of bronchitis every winter, occurring generally about the same time. His voice will be heavy and muffled and the larynx prone to periods of hoarseness. All the symptoms of catarrh are present and possibly asthma, otitis, or at times hay fever, if the upper part of the nostril be at all involved. I have seen the hearing markedly benefited by an operation upon the inferior turbinate.

I had a case in which the patient came under my notice for asthma and after the operation of partial turbinectomy he turned to me one day and asked me if I had treated his ear. I asked him why, and he replied that the ear upon the side I had operated had been completely deaf, although he had had the ear treated for years without benefit, but after the operation he could hear his watch tick when held two feet from his ear. I had not even examined the ear, as the patient had never complained of it, but restoring the nasal passage brought back his hearing. I have seen this occur again and again in others, and to-day in a chosen case of deafness I always advise an operation upon the nose, if the same be indicated.

The nasopharynx should always be thoroughly examined before an operation upon the inferior turbinated bone. An obstruction here will give rise to an anterior stenosis, that will readily clear up, after the vault of the pharynx has been properly relieved of any obstruction that may occur in the locality, such as an adenoid, a posterior nasal polypus, or a fibroid tumor. A hypertrophy of the bone is seldom met with in children, although I have seen it and operated as early as the twelfth year.

Hemorrhages should always be considered in these cases and guarded against as much as possible, both before and after the operation. I will not perform this operation until the patient has been properly prepared and the mucous membrane relieved of all congestion and sign of any inflammatory condition corrected. Years ago I saw the cold snare used to remove only a small fragment of a hypertrophy placed and held in the patient's nose for hours, the loop being gradually shortened by turning the nut, to prevent any alarming hemorrhage. To-day I perform the operation, removing the redundant part of the obstruction and take only a few minutes in the procedure. I do this by preparing my patient for a week or ten days or even two weeks, if there is time, by giving two grains of quinine after each meal and ten grains at bedtime. With the ten grains at bedtime I give twenty grains of potassium bromide in solution. The medicine properly given will reduce the chance of a hemorrhage to a minimum. When the patient first applies for treatment, the turbinated will be found a dark red in color, very much swollen and the canal much narrowed by the swollen membrane encroaching on its lumen. An examination of the anatomy after a week's treatment with quinine and the bromides as directed above, will show the membrane much reduced in size and of a much healthier color. The landmarks of this region can now be distinctly seen. If the nose be still occluded another week's treatment is administered. "*Festina lente*" is a good adage in preparing these patients for the saw. To operate before the patient is properly prepared means a heavy plugging after the operation and the retention of the plug for a period longer than would otherwise be necessary. Then drugs will have very little if any effect on a case of a hemorrhagic diathesis.

These cases are few and far between, and can only be guarded against by going into the history and asking pointed questions before the operation has been commenced. If the mucous membrane fails to cling closely to the turbinated after a two week's treatment with the quinine and the bromides, look for some cause.

One patient who came under my care years ago had the membrane of the nose very much swollen and anemic in color and easily pitted with the probe. An examination of the urine showed a large quantity of albumen. This lasted for six months, when it disappeared and the patient has been free from it ever since. Since that time I have suspected Bright's disease by a nasal examination, and had my suspicion confirmed by an examination of the urine.

Have the mucous membrane as free from inflammation as possible, and the time spent in the purpose draws interest, either during or after the operation of turbinectomy. The local use of cocaine has made the operation perfectly painless; in fact it is as painless as cutting the nails with the scissors, if the cocaine has been applied properly. I first spray into the cavity upon which I am to operate a two per cent. solution of cocaine. I then apply by a probe a twenty per cent. solution of the same drug and allow it to remain on the membrane for about ten or fifteen minutes. This is about the proper time to obtain complete anesthesia in these cases. During this time I may have changed the probe once or twice or even three times, carrying the cocaine well back to the pharynx and well under the growth. I define pain and pressure to my patient. Pain I show him by touching his skin with my nail; pressure I explain by touching his hand and pressing on it with my finger. When the membrane to be cut fails to give any pain, or the scratching of the probe, it is ready for operation. I formerly used the suprerenal capsule or one of its preparations as a spray. It permitted an almost bloodless operation, but the patients were nearly certain to have a secondary hemorrhage after they had left my office. I found that I was often compelled to replug, and the hemorrhage coming on after the patient had left gave rise to fright and alarm on the part of the patient and of his friends, so that in the last few years I have abandoned the use of this drug entirely during operations on the nose. I prefer to see blood follow my knife, so that I can tell how much of a hemorrhage I have under consideration. The instruments that are necessary for a partial turbinectomy are a thin straight saw, one a little heavier than is used in septum work, a pair of strong forceps with a narrow short beak, a nasal snare, and a thin pair of scissors. The blade

or cutting part of the saw should be at least two inches in length. The turbinated bone may be slightly pedunculated or it may have a broad attachment. If the bone be pedunculated the saw is carried under the growth and the cut made from the back forward. After the back part of the growth has been severed, the sawing is done from the back to the front part of the turbinated bone. The sawing is done from below upwards; by using this method, the blood gravitates to the bottom and the part operated upon can be distinctly seen. By cutting from the back forwards there is no reason why the knife should come in contact with the septum, as wounding the part is liable to produce an adhesion later on, especially if the upper part of the wound impinges on the septum. Sometimes the cut part of the turbinated bone can be brought out with the saw after its last cut through the membrane. Blood will now flow freely from the front of the nose and possibly a little may find its way down the back pharynx. I have the patient bend his head over a cuspidor and allow the blood to flow until it shows some sign of diminishing. I now advise the patient to blow his nose to clear it as much as possible. The cut piece generally falls to the lower part of the canal, where it can be seized by a strong pair of forceps and removed. An examination will in some cases show the upper part of the wound too near to the septum; this can be either trimmed off by the snare or a fine pair of scissors. An examination of the nose now will show the turbinate septum space clear and that patency we sought to obtain is provided. Blood may at times ooze through the eye, finding its way there from the lacrymal duct and backing upward, the lacrymal duct opening into the inferior meatus, as I have before stated. The hemorrhage during this operation may be severe, but in the majority of cases not alarming. I now introduce my anterior plugging. I use a piece of absorbent or the plain antiseptic cotton, about six inches in length, the cotton running the length of its fiber. The end I double over slightly and compress it lightly together and mould it before I begin to introduce it into the nose by means of a thin pair of forceps. After I have placed it into the nostril to the space of about an inch, I introduce a smaller piece of cotton to act as a wedge, and I carry this well back to the pharynx, using all the cotton in the plugging.

The hemorrhage has ceased by this time. I examine the pharynx, by the use of the spatula to see if there is any postnasal hemorrhage. I now give the patient in my office ten grains of quinine and twenty grains of potassium bromide and direct him to go home and go to bed and take every three hours a pill containing two and a-half grains each of acetphenetidin and phenyl salicylate. I place him on a light diet of milk or soup and direct him to see me the next morning to remove the plug. A cloth wet with alcohol applied to the forehead after he reaches home is a good expedient. I am very seldom called upon on account of a secondary hemorrhage since I stopped the use of adrenalin, if the anterior plugging has been properly introduced. A posterior plugging of the pharynx is seldom necessary; in fact I do not recall five cases in which I was compelled to resort to this measure.

Upon the morrow when the patient presents himself for examination I begin to remove the plugging. I first draw out one to two inches of the string of cotton; this I cut off with a pair of scissors. If the blood flows freely, I wait a few moments. If the hemorrhage shows signs of lessening, I remove all the plugging. If the cotton is of a bright red color, showing that bleeding is still taking place, I allow it to remain until the following day. After the plug has been removed in its entirety I keep the patient in bed for the remainder of the day. The internal treatment of the quinine and the potassium bromide I continue for two or more weeks after the operation. Two days after the plug has been removed, I clean out the nasal chamber, either with a postnasal syringe or a spray, and direct the patient to let the nose alone as much as possible. Large crusts will collect in the nose, some as large as two inches in length; these will gradually lessen, and when the part has completely healed, which is usually in about six weeks, all crusts will have stopped forming and the normal secretions of the nose are reestablished.

If fresh air could be bottled up, sold at a drug store, and the patient advised to take a teaspoonful every hour, the sale would be enormous and the result most surpassing. The reestablished nasal breathing means a better nutrition, a better supply of oxygen. I have seen patients gain ten, twenty, and even eighty pounds within six months after the operation.

Patient A., female, aged twenty-eight, applied, complaining of asthma, which had developed four years previously. The asthma had been constant for three months, when it diminished, only to reoccur. When she applied for treatment the asthma had been almost daily. An examination of her nose showed the lumen of the turbinated septal space much lessened by the encroachment of the inferior turbinated bone. I advised an operation. Two months after the operation on both her turbinated bones her asthma stopped and she has now gone over two years without any serious attack. I have watched these patients for years after the operation of partial turbinectomy and have never seen any dryness of the pharynx or any condition like an atrophic rhinitis follow.

In treating nasal diseases, I deem it of the greatest importance that there should be in a nose an inferior meatus, unoccupied by foreign growths and capable of performing its function, namely of acting as a drain to the cavity and as a transmitter of air to the lungs. I consider this meatus of so much importance in the economy of the nose, as a drain, that when it is blocked, the secretions dam up the nostril and this state is a salient cause for the reappearance and recurrence of polypi and many headaches that we are called upon to treat. If polypi persist in recurring and the meatus and space are obstructed I operate to restore the space. I have seen a case of antrum disease cured by reestablishing this drain, after syringing through the alveolus process after the removal of a tooth had failed.

Where it has been found that the Politzer air bag or the catheter has given relief to a case of deafness, this operation has shown improvement beyond dispute. If I were to summon up all the various operations that are resorted to in order to correct a nasal obstruction, the one that will give the most permanent relief I would without hesitancy name partial turbinectomy.

I have operated so far on over ten thousand cases, and have still to see one in which the result was not most gratifying and the aim of the operation secured,—perfect nasal breathing and a drain for the nose and all the sinuses that empty into that most important canal, the nostril.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 14, 1906.

THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

THE evolution of this service from a medical bureau in the Treasury Department, organized for the purpose of caring for the sick and injured sailors of the merchant marine, to what is practically the quarantine and public health department of the National Government offers an example of what can be done by hard work and conscientious fulfillment of duty. The surgeons of the service might, without an efficient executive head, have remained to this day what they were intended to be originally—simple hospital internes. How much more they are than this is made manifest in the thirty-fourth annual report, just received, of Surgeon-General Wyman to the Secretary of the Treasury.

That the original purpose of the Marine-Hospital Service is not neglected, in the multiplicity of other duties assumed by the personnel, is shown by the fact that medical relief was given to 57,013 seamen, 14,661 of whom were treated in the hospitals and 42,352 as out-patients. There are twenty-one hospitals officered by the surgeons of the service, and 120 other relief stations where seamen receive hospital and dispensary treatment; there is also a tuberculosis sanatorium at Fort Stanton, N. M., where 385 patients were cared for during the year. One hospital has just been completed at Savannah, Ga., and the plans for two others, at Buffalo, N. Y., and Pittsburg, Pa., are now in course of preparation. In addition to the medical relief work, upwards of 5,000 physical examinations were made of seamen and of candidates for employment in various services, such as the Revenue-Cutter, Light-House, Life-Saving, Philippine Islands, Isthmian Canal, etc. During the year 1,026,499 aliens were inspected by officers of the Service to determine their physical fitness for entry into the country. The work of the Hygienic Laboratory has been of the greatest importance, and its development during the past year has been notable. As now organized, the laboratory is prepared to investigate all public health problems from the standpoints of pathology, bacteriology, zoology, pharmacology, and chemistry. The scientists connected therewith have established a diphtheria antitoxin unit which is now the standard for this country; a specimen of every make of vaccine virus in the market is examined once a month for potency and purity, the result of which has been a marked improvement in the quality of this important prophylactic. The division of zoology has investigated the spotted fever of Bitter Root Valley, in Montana, and has studied ankylostomiasis in this country and, in collaboration with the Army Medical Department, in Porto Rico; it has also investigated the reported prevalence of the dwarf tapeworm (*Hymenolepis nana*). The division of pharmacology has made numerous experiments with the nitrites, alcohol, and a new quinine derivative, has analyzed all the drugs and chemicals purchased by the purveying bureau, and has made certain experiments on the pharmacological action of sulphur compounds, on the functions of the thyroid gland, and on the relation of carbohydrates to acetone intoxication and the cause of diabetes. In the division of pathology and bacteriology many important subjects were investigated. The division of chemistry was organized in June of last year and the workrooms are now being equipped to carry on this part of the work. The administration of national quarantine has been continued in Porto Rico, Hawaii, and the Philippines, and medical officers of the service are stationed at a number of Cuban, Central and South American ports, in the offices of the American Consulates in certain ports of Japan, China, and India, and in Naples. At the request of the authorities of several of the maritime States, their quarantine service has been taken over by the officials of the Public Health and Marine-Hospital Service. The excellent work in repression of the yellow-fever epidemic at New Orleans, done by Surgeon White and others of the service, is too fresh in the memory of all to call for detailed reference.

Space forbids further consideration of the great work of safeguarding the health of the country accomplished by Dr. Wyman and the trained corps of scientists constituting the Public Health and Marine-Hospital Service, but what has already been done suggests almost unlimited possibilities for the future. The act just passed by Congress, placing the service in charge of any future yellow-fever epidemics in the South, might well be amplified so as to raise the service from the subordinate position of a bureau of the Treasury Department to an independent Department of Public Health. If the supervision of proprietary medicines, recently assumed by the irresponsible Council on Pharmacy and Chemistry of the *Journal of the American Medical Association*, were entrusted to the division of pharmacology of the Public Health Service, it would at once command the respect of the entire medical profession of the country, for the suspicion of partiality which now blights the work would be removed.

This brief review of the work of the Marine-Hospital Service should be of special interest to the young men who are now being graduated from the medical colleges of the country and must soon decide what career within their chosen calling they will adopt. The service offers at this time unusual opportunities for the young physician whose ambition it is to do something more in the world than merely treat the sick—high and noble as such a career is. The highest and noblest of callings is undoubtedly that of the family physician—higher, even from the viewpoint of the man of earnest religious convictions, than that of the clergyman—but all cannot adopt the counsels of perfection. The pure scientist is needed in the world, as well as the minister to human suffering, and to the young medical man whose bent is in this direction the Public Health and

Marine-Hospital Service offers unusual advantages, its work embodying all forms of medical activity, from the practical therapeutics of the marine hospitals to the pure science of the laboratories. It also offers the opportunity of foreign travel in the West Indies, Asia, and Europe, including our own possessions, as well as that of an acquaintance with all parts of our own country, from Maine to California and from the Gulf of Mexico to the Great Lakes. Last, but not least in this practical world, admission to the service assures a comfortable living. The assistant surgeon, from the day of his appointment, receives a salary of $1,600 per annum, and after five years, if he has done good work enabling him to pass the examination for promotion to the grade of passed assistant surgeon, his pay is $2,000. From this time on promotions are made to higher grades, as vacancies occur, the salary increasing with the rank, up to $5,000; but independently of this increase of rank, all officers receive a 10 per cent. increase of pay with each five years of service. In addition to this, the officers are provided with comfortable quarters, or, when this fails, they are allowed commutation ranging from $30 to $90 per month, according to rank and station. The Marine-Hospital surgeon has an advantage over his colleagues in the Navy, in that he may marry with a reasonable assurance that his home will not be broken up by assignments to distant stations. Of course, he may be sent abroad or transferred to some other part of the country, but such assignments are usually for long periods, and he can therefore take his family with him; he receives a liberal allowance for traveling expenses, which he can make, with economy, cover much of the expense of transportation of his family and household effects. The recent graduate, to whom the work of the Marine-Hospital Service, as we have here outlined it, is attractive, will do well to secure this report of Surgeon-General Wyman and study it in order to learn more fully what his duties in the service would be, that he may decide, in the beginning of his career, whether or not he will take it up for his life work. He might do much worse, and yet, unless the work there outlined appeals to him strongly, he had better turn his attention to pure practice either in general medicine or in some specialty.

A NEW VIEW IN REGARD TO INFLAMMATION.

Teachers of pathology nowadays are usually at considerable pains to impress their pupils with a realization of what has been aptly termed the conservatism of inflammatory processes. The student is encouraged to believe that inflammatory changes do not of themselves constitute a primary state of disease, but rather that they are the consequence of an insult of one sort or another to the bodily machine and represent the effort of the organism to minimize the effects of the injury. While the sufferer from, say a furuncle, very naturally regards the local evidences of the disorder which are evident to his senses in the classical syndrome of pain, swelling, redness, and heat, as his chief cause of grievance against an unkind fate, the more perspicacious gaze of the pathologist views these manifestations as so many indices that the body is marshaling its resources in order to put to rout a horde of invading bacteria ensconced in some hair follicle or similar recess. In brief, to use the words of a well-known writer, inflammation is regarded as the local attempt at the repair of injury, and, though it may sometimes overshoot the mark and produce undesirable consequences, its purpose is on the whole beneficent and tends toward the welfare of the individual. That this point of view is a novel one, to the public at least, is shown by the astonishment evinced in the comments of the lay press on a recent address delivered by Sir Frederick Treves, in which the speaker dwelt upon the value of peritoneal or pleural adhesions, effusions in inflamed joints, etc., as means of facilitating the process of repair.

The principle involved in this view is a broad one and accords well with the demonstrations of morbid histology as well as theories of immunity, cytolysis, etc. A recent writer, however, Spiess (*Münchener medizinische Wochenschrift,* February 20, 1906), presents some suggestions on the subject of inflammation in which these beneficent attributes of the several phenomena involved receive scant courtesy. Starting with the clinical observation that in cases of operation on the nose or throat in which all pain both in the course of the procedure and during the period of healing was suppressed by the very free use of local anesthetics, no inflammatory reaction was noted, Spiess suggests that all manifestations of this nature are evoked purely by centripetal stimuli emanating from the point of injury, and if these are abolished no reaction can follow. In support of this belief he refers to the well-known immunity to inflammatory processes exhibited by patients with hysteria or anesthesia due to mental disorders. Laparotomy wounds in the insane heal without complications even though contaminated by the filthy hands of the patient; the Hindoo fakirs can perform their self-mutilations with impunity, and a patient of the author's with hysterical anesthesia could plunge the hand into boiling water without giving rise to the ordinary accompaniments of a burn if the act was performed during an access of anesthesia. If sensation had begun to return a scald was produced. Experiments on anesthetized animals led the author to the same conclusion; that is, that inflammation does not follow if it is possible to cut off all centripetal impulses from an injured part, and that already existing inflammations are caused to subside rapidly through anesthetization of the inflammatory focus. The method of anesthesia must affect only the sensory nerves, however, and should not interfere with the ordinary vasomotor mechanism. The success of Bier's method of treatment by hyperemia is attributed by the author solely to the relief of pain that is secured by the procedure.

POLLUTION OF THE TIDAL WATERS OF NEW YORK.

A movement has recently been inaugurated by a number of sanitarians and public-spirited citizens of this city to devise means for preventing the pollution of the waters of New York Bay and its estuaries. Up to the present time no concerted action has been taken for guarding these waters against pollution.

It is true that the emptying of garbage and other solid refuse within the harbor is restricted by the United States Government, but the object here is only to insure a proper depth of water for navigation.

The idea of establishing a Metropolitan Sewerage Commission is the outcome of preliminary investigations which have been carried on during the last three years by the New York Bay Pollution Commission. This commission has found that the upper bay and neighboring waters bear evidence of being seriously contaminated by sewage and that in some localities the pollution is so great as to give rise to an actual nuisance. Examples of such conditions are the Harlem River, Kill van Kull, mouth of the Bronx River, Newtown Creek, and Passaic River near Newark. The odors which arise from Gowanus Canal, in Brooklyn, are so offensive that extensive works are about to be constructed to purify this arm of the bay.

At the present time about 455,000,000 gallons of sewage are emptied into the tidal waters within a radius of twenty miles of the New York City Hall every day. The solid matter so contained is equivalent to over 1,500 tons of dry sludge, about one-half of which is decomposable organic matter. It is estimated that by the year 1930 there will probably be not less than 10,000,000 inhabitants in the metropolitan district, and with this increase in population will come a corresponding increase in the pollution of the tidal waters.

The desirability of keeping the waters of New York and vicinity in the purest condition practicable is made evident by a consideration of the peculiar situation of the city and the many uses to which these tidal waters are put. The number of passengers transported across the waters of the New York district in 1905 was nearly 200,000,000. The free floating baths maintained by the city along the water front are patronized by over 3,500,000 bathers every year. Floating hospitals carry 35,000 persons and give thousands of baths with water from the bay for the benefit of the sick every summer. Great numbers of people who live in the densely crowded sections of the city frequent at night the recreation piers along the water front; the number of visitors to one of these piers alone has been known to exceed 8,000 in a single evening. It is estimated that at least a million bushels of oysters are gathered annually from the tidal waters within a radius of twenty miles of the New York City Hall; the relation of typhoid fever to infected shellfish is now so well established that the oyster industry may eventually, and should be, driven from this vicinity if further pollution is not prevented.

In order to provide for the protection of the bay, it is proposed that a Metropolitan Sewerage Commission be appointed by the Governor. This Commission will be authorized to confer with a similar Commission from New Jersey, to the end that the two States may cooperate in bringing about the protective measures required. A bill providing for such a Commission has been drafted and has been endorsed by the Chamber of Commerce of the State of New York, the Merchants' Association, the Maritime Association, the Board of Trade and Transportation, and the Produce Exchange. The bill should also receive the endorsement of the New York Academy of Medicine and other representative medical societies of the five boroughs, and we are sure the physicians of Jersey City and Newark will take similar action in relation to a cooperative bill to be brought before the New Jersey Legislature.

Can the Cerebral Cortex be Stimulated Chemically?

It has been claimed that the application of certain substances—creatin, urinary sediments, etc.—directly to the surface of the brain may produce muscular contractions, and this fact has been employed as an explanation of eclampsia and similar states. S. S. Maxwell, in a recent communication (University of California Publications, Vol. 3, No. 3), claims that these experiments are open to objection as evidence of chemical stimulation of the cortex because a relatively long interval elapsed between the application of the chemicals and the production of the contractions, affording sufficient time for an osmotic action to take place by the abstraction of water from the tissues, and thus, by diffusion, permitting the dissolved substances to act upon the underlying white matter of the corona radiata instead of upon the cortex. The materials employed were also unsuitable for the purpose, as they did not belong to the class of substances now known as nerve stimulants. Maxwell made a series of experiments with substances whose anions precipitate calcium, as Loeb had shown that chemical stimulation was best accomplished by these, namely, the soluble citrates, oxalates, fluorides, oleates, etc. It was found, however, that no chemical stimulation of the cortex was obtained, but that a reaction was promptly elicited when the solutions were injected so deeply as to act directly upon the white matter. The response, in contrast to what had occurred in previous experiments, was almost instantaneous, and the movements were as definitely localized as in the case of electrical stimulation. The absence of irritability of the cortex to mechanical stimulation is well known through clinical and surgical experiences, and these observations show that the gray matter, or at least its outer portion, is equally insensitive to chemical stimulation. The question may now be raised whether electrical stimulation really occurs or whether the cortex is entirely devoid of irritability, for Loeb has claimed that that electrical stimulation acts through changes in the concentration of the ions, possibly the calcium precipitates, and hence is apparently of the same nature as chemical stimulation by the latter. The spreading of the lines of force, however, make it impossible to determine whether the excitation by the electrical current has occurred in the cortex or the underlying gray matter. Further researches on this topic are promised by the writer.

News of the Week.

Plans for a Filtration Plant.—The city water commissioner has submitted to the mayor preliminary details of a plan to build a filtration plant in conjunction with the Jerome Park reservoir. The plan is intended as an alternative one to that proposed by the Burr-Hering-Freeman commission. This body suggested the taking of a site two or three miles southeast of Tarrytown. It was estimated that a 250,000,000 gallon plant in this locality would cost $8,500,000 and that a 500,000,000 gallon plant would cost $15,000,000. According to the present proposal there is no

need for the purchase of new land, as part of the land bought by the city for the Jerome Park reservoir can be utilized. It is also stated that this plan would save much time and cost, and that the danger of contamination of filtered water during the passage from the more distant beds would be avoided. The project has been submitted to the Board of Estimate.

To End Shotgun Quarantines.—The House of Representatives on April 3 by a vote of 202 to 26 passed the National Quarantine bill which was slightly modified from the form in which it was passed by the Senate on the day before. The bill places the control of all quarantine stations, grounds, and anchorages under the Secretary of the Treasury, and directs that as soon as practicable after the approval of the act he shall select and designate such suitable places for them and establish the same at such points on or near the seacoast of the United States on the Mexican border as in his judgment are best suited for the same, in order to prevent the introduction of yellow fever into the United States. The bill further gives the Secretary of the Treasury the right to establish a quarantine station at the Dry Tortugas Islands, and at such other points at or near the seacoast (not to exceed four in the aggregate) as he deems necessary. The bill also provides that every common carrier engaged in inter-State commerce shall receive and carry through any State or Territory passengers, freight, and baggage which may have been discharged and properly certified in accordance with the regulations of the Public Health and Marine Hospital Service, and every person interfering with or obstructing such carrier or any passenger or any instrumentality of commerce in any such carriage or journey shall be guilty of a misdemeanor, and on conviction be punished by a fine not exceeding $300, or be imprisoned for a period not exceeding one year, or both, in the discretion of the court. The passage of the measure was bitterly opposed by the representatives of some of the Southern States on the ground that it interfered with State rights.

To Raise the Standard of Immigrants.—The House Committee on Immigration and Naturalization has agreed to a favorable report on the Gardner immigration bill. The measure raises the head tax from $2 to $5, and provides an educational test for immigrants, requiring every person above the age of sixteen years admitted to the United States to be able to read some language. It requires that every adult male immigrant shall have at least $25 in money at the time of landing and every female adult immigrant at least $15, but heads of families may be admitted with their entire families provided they have $50. It places in the excluded class imbeciles, the weak-minded, and manual laborers of poor physique, and gives the Department of Commerce and Labor discretion to admit or exclude immigrants under sixteen years of age coming to this country alone.

United States Civil Service Examinations.—The United States Civil Service Commission announces an examination on June 6 and 7, 1906, to secure eligibles from which to make certification to fill at least two vacancies, at $600 per annum each, with maintenance, in the position of medical interne, Government Hospital for the Insane, Washington, D. C., and vacancies as they may occur in any branch of the service requiring similar qualifications. The Department states that it reserves the right to continue or terminate appointment at the end of one year, or to promote the appointee at the expiration of that length of service. This examination is open to all citizens of the United States who are over twenty years of age, are graduates of reputable medical colleges, and comply with the requirements. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application form 1312.

The Sixteenth International Medical Congress.—The Hungarian government has authorized the Hungarian delegates to the Fifteenth International Medical Congress at Lisbon to extend an invitation to hold the Sixteenth Congress in 1909, in Budapest. The Hungarian government has allowed a sum of $25,000 for covering the expenses, and the same sum has been voted by the General Assembly of the city of Budapest. The invitation will be transmitted by the president of the Hungarian committee, Mr. L. de Toth, Counsellor in the Ministry of Education.

Institute for Tuberculosis Incorporated.—The Chicago Tuberculosis Institute was recently incorporated by Drs. Edward B. Bicknell, Arnold C. Klebs, and Henry B. Favill. It is the intention of the organization to establish a free dispensary, to collect statistics, and carry on an active educational campaign. Dr. Henry B. Favill has been elected Chairman of the Board of Trustees.

Gift to Newberry Library by Dr. Senn.—The working library of Professor Meissner on internal medicine, and a botanical library of three hundred or more volumes, consisting mainly of old and classical works on herbs, have been donated to the Newberry Library, Chicago, by Dr. Nicholas Senn.

Physicians Oppose Contract Work.—Physicians of Racine (Wisconsin) have pledged themselves not to take any more contract work, insurance, lodge, or otherwise, during this year. The opposition raised by certain lodges, factories, and insurance companies has now subsided, the local press having made it clear to the public that the people will be the gainers by doing away with medical contracts.

Dr. Henry Leffmann has been appointed a member of the Philadelphia Board of Health in succession to Dr. Charles B. Penrose resigned.

A Smallpox Patient was discovered in the Jersey City Hospital last week, and in consequence all the inmates of the institution were vaccinated.

Typhoid Fever in Pittsburg.—The epidemic of typhoid fever in Pittsburg has assumed very alarming proportions. Several hundred cases have already been reported, 56 having been discovered in one day. The outbreak is attributed to the swollen condition of the local rivers and it is expected that the situation will be difficult to control until the floods subside.

Health Conditions in the Canal Zone.—The effectiveness of the sanitary régime on the Isthmus is shown by the fact that in spite of the existence of yellow fever in neighboring ports on both the Caribbean and Pacific sides there are no cases of the disease along the canal route. The health report for February submitted by Col. Gorgas shows a sick rate of 20 for each 1,000 of the 23,000 canal employees. There were 56 deaths among canal employees, and of these 49 were negroes. The death rate among employees shows an annual rate of 30 to each 1,000 persons. The death rate among non-employees was 42 per 1,000.

Pneumonia and malarial fever were the chief causes of death.

A Bequest to St. Luke's Hospital.—St. Luke's Hospital in this city receives $15,000 by the will of Mrs. Sarah A. Sands who died at Lakewood, N. J., on March 30. Three beds are to be endowed in memory of the testator's husband, Abraham B. Sands.

A Peculiar Skin Affection.—Travelers to the Orient are not infrequently discommoded by a form of dermatitis ascribed to contact with freshly lacquered objects. From Cambridge, Mass., comes a description of an apparently somewhat similar affection occurring among the workmen in a local furniture factory. The men were at work on a large quantity of a peculiar wood termed tonquin, which had been imported from the Philippines. Those who inhaled the dust or handled the wood suffered from asthmatic attacks and an irritating rash on the exposed surfaces of the body. Twenty-eight employees were affected.

Jefferson Medical College.—Dr. Edward Anthony Spitzka who for two years has been a demonstrator of anatomy at the College of Physicians and Surgeons in this city, has been elected professor of general anatomy, and Dr. George McClellan professor of applied anatomy at the Jefferson Medical College, Philadelphia.

To Incorporate Institutions for the Relief of the Blind.—Two organizations are seeking articles of incorporation from the State Board of Charities in order to found a society for the relief of the crippled and the blind. They are the New York State Association for the Promotion of the Interests of the Blind and the Crippled Children's East Side Free School. It is stated that there are 865 blind persons in Manhattan and the Bronx, of whom 460 have expressed a desire to enter such an institution as it is proposed to establish.

Dr. J. H. White of the Public Health and Marine Hospital Service has been presented with a silver service by a large number of the citizens of New Orleans in recognition of his services to the city during the recent yellow fever epidemic.

Dr. Francis J. Quinlan of this city has received the Lætare Medal for this year of Notre Dame University of Indiana.

A New Montana Society.—A Tri-County Medical Association representing the counties of Custer, Rosebud, and Dawson, was formed at Miles City on March 18. The officers are as follows: *President,* Dr. Andrus; *Vice-President,* Dr. Hathaway; *Secretary and Treasurer,* Dr. Huene.

Iowa Tuberculosis Sanatorium.—The Iowa House of Representatives has passed a bill appropriating $50,000 for the establishment of a tuberculosis sanatorium, the site to be decided on later.

Oklahoma University.—The medical school of this university was admitted to membership in the American Association of Medical Colleges at the meeting recently held in Pittsburg.

Commencement Exercises.—At the graduation exercises of the Dartmouth Medical School held on March 31, the degree of M.D. was conferred upon ten candidates. The Atlanta College of Physicians and Surgeons at its fifty-second annual commencement on April 2 graduated a class of fifty-two, and the newly-organized Atlanta School of Medicine on April 3 conferred its degree on its first class, consisting of twenty-one students. The graduating class of the Medical Department of the University of Nashville, that held its commencement exercises on March 28 numbered forty-two.

Railway Transportation of the Sick in Germany.—The Prussian Minister of Railways has issued an edict concerning the transportation of the sick on railroad trains. Suitable stretchers are to be provided on which the patient may be carried without any transferring from his house to the train, and from the latter to his ultimate destination. The stretchers may be introduced only into third-class compartments. Two third-class fares are to be paid for the patient and stretcher, and one third-class fare for the attendant.

In Honor of Professor Nitze.—In order to commemorate the death of Dr. Max Nitze, the inventor of the cystoscope, which occurred on February 22, a memorial service attended by his friends and pupils was held in Berlin on April 1. An exposition has also been held to show the development of cystoscopy, making use of the material collected by Nitze.

The Prophylaxis of Venereal Diseases.—The German Society for the Prevention of Venereal Diseases has in the past two years distributed over a million copies of its circulars of warning and instruction. This has been effected through officials of various sorts, physicians, the dispensaries, sick lodges, and in the army, so that young men of all classes have been reached. It is now proposed to issue a second circular intended for the counsel of young women, working girls, servant maids, salesgirls, etc., who, through ignorance, are exposed to danger from this direction.

Waukegan (Illinois) Medical Association Organized.—At a meeting, held March 12, physicians and dentists of Waukegan and North Chicago organized an association with this name. The following officers were elected: *President,* Dr. Edward F. Gavin; *Vice-President,* Dr. Jacob F. Roemer; *Secretary,* Dr. Beatrice Pierce; *Treasurer,* Dr. Wm. S. Bellows, all of Waukegan, and *Executive Committee,* Drs. L. H. Tombaugh and Chas. E. Daniels, Waukegan, and Dr. Fuller, North Chicago.

Obituary Notes.—Dr. Andrew B. Stevens of Watertown, N. Y., died on April 7, at the age of sixty-six years. He was a veteran of the Civil War.

Dr. J. D. MacCallum of San Francisco died on April 6 at the age of thirty years after an illness due to nephritis extending over a period of three years. Dr. MacCallum was assistant to Dr. Jacques Loeb in the department of physiology of the University of California, and had left unfinished several important pieces of research which some of his colleagues expect to complete and publish.

Dr. J. A. Cronin of Boston, Mass., died on April 2, after a long illness. He was a graduate of the Bellevue Hospital Medical School.

Dr. A. J. Weathered of Waco, Tex., died suddenly in his office on March 27 at the age of fifty-four years. Dr. Weathered had practised in Osceola, Tex., for some years and came to Waco fourteen years ago.

Dr. Joseph Byron Kingsbury of Brocton, Mass., died on March 24 at the age of seventy-one years. Dr. Kingsbury was born at Braintree, Vt., and was a graduate of Dartmouth College and Medical School. He had practised in Braintree for thirty-two years, and during this time occupied many public positions.

Dr. A. C. M. Moir of Newton, Mass., died on March 29, at the age of thirty-one years. He had previously practised in Waban, Mass., removing to Newton in 1900.

Dr. W. H. K. King of Carthage, Mo., died on

March 22, at the age of sixty-two years. He was born in Pittsburg, Pa., and was graduated from Rush Medical College in Chicago.

Dr. A. S. Elwood of Denver, Col., died on March 31 at the age of seventy-nine years. Dr. Elwood enlisted in the 40th Iowa infantry in August, 1862, and was commissioned as assistant surgeon on the regimental staff, serving in that capacity until mustered out because of disability a year later.

Dr. Eugene J. B. DuGas of Roseburg, Ore., died on March 27, at the age of fifty-nine years, after a long illness from a gastric affection. Dr. DuGas was born in Augusta, Ga., and after graduating in medicine served in a professional capacity in the Confederate Army, enlisting with his father who was also a surgeon. Shortly after the close of the war Dr. DuGas moved to Oregon, and settled in Roseburg fourteen years ago.

Dr. Michael P. O'Neill died at Philadelphia of typhoid fever complicated by pneumonia on April 3 at the age of thirty years. He was graduated from the Medico-Chirurgical Hospital in the class of 1900. He was for several years Chief Resident Physician in St. Agnes Hospital and at the time of his death was a member of the visiting staff of the Hospital. He was also on the surgical staff of the Medico-Chirurgical Hospital.

Dr. Edwin G. Hawkes died at Philadelphia on April 6 at the age of forty years. He was graduated from Jefferson Medical College in the class of 1892.

Dr. Jefferson D. Christman died at Allentown, Pa., on March 30 at the age of fifty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1876.

Correspondence.

THIRD ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

ADDRESS OF WELCOME—SCARCITY OF MEDICAL PRACTITIONERS—THE CHOLERA—THE HEALTH AUTHORITIES OF THE ISLANDS—PRESIDENTIAL ADDRESS ON THE PROGRESS OF MEDICINE IN THE PHILIPPINES—ST. PAUL'S HOSPITAL, MANILA—THE LEPER COLONY—ADVANCES IN TROPICAL MEDICINE.

Manila, P. I., February 28, 1906.

The third annual meeting of the Philippine Islands Medical Association was begun this afternoon under most favorable auspices, at the library of the Bureau of Science, on Calle Herran. The House of Delegates met at 3 P. M., and a committee was appointed for the purpose of making recommendation as to whether it would be better to publish the proceedings of the association in the *Philippine Journal of Science*, or whether it could afford to make a separate publication of this matter. A committee on nominations was appointed for the purpose of selecting the names of persons to be submitted to the House of Delegates at its next session, for consideration in connection with the appointment of officers for the ensuing year. The patent and proprietary medicine evil, and the advisability of recommending legislation for the preventing of the refilling of prescriptions, and to make it an offense to sell impure or adulterated drugs was informally discussed. After the transaction of some other routine business the House of Delegates adjourned.

At 4 P. M. the first general meeting of the association was called to order by the president, Dr. Victor G. Heiser, after which the Reverend Bishop Charles H. Brent offered a prayer. The Governor-General then followed with some opening remarks, which were delivered in a particularly happy strain. In general, he congratulated the members of the association on the progress that had been made during the year, and remarked how dependent the people of the Philippine Islands were upon the medical profession. He stated that the white man could now live in comparative safety and comfort in tropical countries, owing to the many safeguards which were thrown around him by the ever-alert physicians. He also remarked the deplorable lack of medical men in the Philippine Islands, for combating the many diseases with which we are confronted, and expressed the hope that the new medical school, for which provision had been made by the Commission, would, in a few years, be able to supply this need.

The Governor-General was followed by the Secretary of the Interior, the Honorable Dean C. Worcester, who delivered an address, and stated that it was hardly possible to exaggerate the importance of medical work in the Philippine Islands; that we are constantly menaced with the introduction of dangerous epidemic diseases from the neighboring Asiatic coast, and must depend upon the quarantine service to protect us from them. He stated that we have, at present, in the islands, cholera, bubonic plague, and smallpox, and must look to the representatives of the medical profession to hold these diseases within the narrowest possible limits, and stamp them out within the shortest possible time. The medical profession is called upon to combat the various afflictions peculiar to, or aggravated in hot regions, which are commonly known as tropical diseases; that the people here were all too scarce; that while race suicide was by no means common, yet we were confronted with a horrible infant mortality, which made the increase in population painfully slow; that in combating the aforementioned conditions there are encountered at every turn ignorance and prejudice of the people, who, until recently, were wholly unaccustomed to modern sanitary measures, and as yet little appreciate their beneficent influence.

He stated that the number of medical practitioners, good, bad, and indifferent, was absurdly small. There was one physician to every 18,399 inhabitants, and that, outside of Manila, there was only one to each 50,455 inhabitants, and in a number of provinces there was no medical man of any description. A great many of the inhabitants of these islands die without medical attention, and a great many of them of curable diseases. He stated that meetings like the present one of the association have made it possible to foster cooperation between physicians and the interchange of knowledge born of experience. He stated that the Japanese had conferred incalculable benefit upon medical science by their practical demonstration of what could be done in combating epidemics and in protecting the health of soldiers in the field, and, from the day of the establishing of civil government in these islands, the relation between the medical officers of this Government and those of the Japanese Government had been of the friendliest and most helpful character; that in the early days serums and prophylactics were furnished by the Japanese; that representatives of the Bureau of Science who were sent to Japan to study their methods of serum manufacture, and to work in Government hospitals, had invariably been treated with great courtesy and consideration, and had been assisted in every possible way. He stated that it was therefore with special pleasure that he welcomed here to-day Dr. Shiga, one of the most distinguished among the many distinguished scientific investigators of Japan, and that to him we owed a special debt of gratitude for his prophylactics, which have now been long manufactured here and so successfully used in combating bubonic plague; that, owing to the outbreak of plague in Osaka, we had been deprived of the pleasure of welcoming Dr. Kitasato, another Japanese scientist of world-wide reputation, who would have been with us had not the call of duty detained him, but he had sent a valuable paper to be read before the association.

He said that we had representatives with us from the country where the newest efforts to apply modern methods were being made, and of the country where these methods have, in many particulars, reached their highest development, and only good could come of such a meeting.

In the early days of the present cholera outbreak the disease appeared in Bilibid Prison; that the physician in charge of that institution, aided by two other physicians assigned from the Bureau of Health, and by another especially employed to meet the emergency, made vigorous efforts to check the disease, but without success, they being compelled to work under the general control of the warden, a faithful and efficient officer, but who was without scientific experience in dealing with epidemics; that on September 1 he suggested to the Secretary of Commerce and Police the desirability of putting the Director of Health in direct control of the sanitary matters in Bilibid, which was done; that on September 2 the Director of Health thoroughly inspected the premises and ordered sanitary repairs, which were promptly carried out. The last case of cholera occurred on September 5, three days after he had taken charge; that this striking result led him to recommend to the Philippine Commission that the Director of Health be placed in permanent control of the sanitary matters of Bilibid, where conditions were far from satisfactory, the death rate having been 128 per thousand during June, 148 per thousand during July, 188 per thousand during August, and 242 per thousand during September. The recommendation was favorably acted upon, and the Director of Health

assumed control. The death rate for October was 124 per thousand; for November, 123; for December, 64; and for January, 46, as against 82 for January, 1905. He stated that he knew of no more effective demonstration of the value of the application of modern scientific methods in combating disease than the ones just mentioned. He stated that the work of the Director of Health and subordinates, in fighting against cholera in the city of Manila, and in the neighboring provinces, during the past year had been beyond praise. Marine quarantine had proven absolutely effective in preventing the spread of the disease to other islands. The early course of the disease was almost precisely similar to that of the epidemic of 1902. The first cases were very fatal and the number steadily increased. Profiting by past experience, no effort was made to establish a land quarantine, or to isolate contacts. The Bureau of Health concentrated its efforts upon securing the early discovery of all cases, and the prevention of the spread of contagion by most thorough disinfection of premises, clothing, etc., and by the removal to the cholera hospital of those attacked when they could not be safely taken care of at their homes.

Hardly was such a policy fairly established when the number of cases in the city of Manila began to decrease, and was soon reduced to one or two per day, which were usually to be anticipated long after the danger of a general epidemic was over. As the result of the wise policy pursued, fear of the hospital was minimized, relatively few cases were concealed, and the effective cooperation of the Spanish and Filipino physicians secured. Taking into consideration the limited number of medical men available, it was evident from the outset that it was necessary to depend upon an effective campaign of education to prevent the disastrous spread of the disease to the provinces. A set of instructions, explaining in simplest terms how even the poorest people might avail themselves of means always at their disposal effectively to protect themselves from cholera, were prepared, translated into Spanish and the more important native dialects, and circulated throughout the islands; that the public school system furnished the most effective means for distributing these directions. They were taught to the children, who were instructed to tell their parents what they had learned. His Grace, the Archbishop of Manila, not only caused these instructions to be distributed through the agencies at his command, but himself visited the cholera hospital, and directed the priests in Manila to call attention to the fact that this institution offered the best and wellnigh only hope of recovery to those attacked with the disease. The agents of the Bureau of Health visited the towns that were most severely stricken, and by tireless, patient, and persistent effort and rare tact persuaded the municipal officials and private citizens to do their duty; as the result of which cholera has been held in the closest check; that all this has been accomplished without entailing any appreciable or unusual expenditure.

The duties incident to safeguarding the public health of the islands were divided between the Bureau of Health and the Bureau of Science, the latter bureau being specially charged with the diagnosis, by laboratory methods, of those cases which presented the most obscure and difficult symptoms; also to the manufacture of sera and prophylactics required for the work of combating disease. He stated that on the first day of the last annual meeting of the association the machinery of the laboratory building was operated for practical purposes for the first time; that during the period which had elapsed enormous advantages had accrued from the improved facilities afforded by the modern laboratory building and the equipment installed therein; that although the medical men at the laboratory had been, at times, well-nigh overwhelmed with an enormous amount of routine work, nevertheless they had found time to carry on original investigations, and the results achieved attracted wide and favorable attention throughout the scientific world. Especially important had been the preparation, by the Director of the Biological Laboratory, of cholera vaccine, which had been proven to produce an extraordinarily high blood immunity against that disease, and which might be employed without causing any serious reaction. The vaccine had been used on a large number of prisoners in Bilibid, but, fortunately for them, and unfortunately for the cause of science, the Director of Health had stamped out cholera at that institution at the very time the vaccinations had been performed, so that there were no further cases there either among vaccinated or unvaccinated inmates. Recently it had been tried in a number of towns in the provinces, and it was hoped that some more definite and scientific data would shortly be available.

During the year the Bureau of Science had started a journal known as the *Philippine Journal of Science*, in which were published the results of investigations which had heretofore been published in special bulletins of the bureau.

The hospital question still remained a serious one. The Civil Hospital, which has recently been transferred to the Bureau of Health, still continued to occupy unsatisfactory quarters on a most unsatisfactory site, but it was hoped before this association would meet again that at least ground would be broken for a modern hospital. The situation here, however, had been relieved to a large extent by the opening of the St. Paul's Hospital.

The address of Mr. Worcester was followed by an address on "The Progress of Medicine in the Philippine Islands," by Dr. Victor G. Heiser, president of the association. He stated that the health of any community, or of any country, was its most valuable asset, and that the truth of this proposition applied with special force to the Philippine Islands, where so much had been lost, so much delayed, and so much was to be gained by health conditions. If cholera, rinderpest, and surra had not appeared, the historian in these islands would have had quite a different story to tell. These diseases were, in a large measure, responsible for the depression in business, the timidity of capital, and the spirit of unrest, of which too much had already been said. Medical science held the key to the prosperity of the Philippine Islands; that whatever might be the relative importance of the medical man in other parts of the world, he, and the profession he represented, stood first in this country; that to be without health was to be without earning capacity; that public health was an economic asset of the highest possible value, contributing to the economic strength of the people, furnishing the foundation upon which the entire superstructure of municipal life and credit was built. A strong people, relieved of unnecessary burdens caused by sickness and death, could bear other and larger burdens, which would advance them just that much over their competitors.

Medical progress in the Philippines might be divided into three parts, the first, beginning with the Spanish occupation and extending to 1876; the second period, from 1876 to 1898, and the third, beginning with the American occupation and extending to the present time. During the first period physicians were imported, to a large extent, under church or government control. They came and they went, each one contributing something to impress upon a mistrusting people the beneficent intentions of the most charitable and self-sacrificing profession the world has yet known; that modern quackery was scarcely known—and even to-day it might be said there were fewer irregular practitioners in the Philippines than almost any other country in the world. The second period began with the graduation, in 1876, of the first class from the medical department of the Santo Toma's University, the graduates of which held sway until 1898, when the American doctor appeared upon the scene; that, with the beginning of the present period, 1898, a new order of things was established. The microscope supplanted the sword, the martial spirit gave place to the research habit, and the status of social and political prominence, to self-sacrificing obscurity, until to-day, the medical man in the Philippines, like the medical man the world over, is struggling in the race of life, with no hope beyond that of being granted the sacred privilege of helping his fellow-man.

He stated that the last year had been of great importance in its relation to local medical progress. The passage of an act by the Philippine Commission, establishing a medical school and defining the manner in which it should be controlled and conducted was probably the most important; that the establishment of this school marked a new era in the progress of medicine in the Philippine Islands, and, in time, would prove to be the best investment that the Philippine Commission could possibly have made; that the Philippines, with an educated native doctor for every thousand inhabitants, would be a different country with a different history; that American, European, or other foreign physicians were not needed, but educated Filipino sanitarians.

He stated that the Philippines might well profit by the lesson offered by Japan in its recent war with Russia; that almost the entire success of the campaign rested upon the fact that every Japanese who fell must die upon the field of battle; that the Philippine Medical School would do for the Philippines what the Japanese schools had done for Japan, and would prove a blessing to the people, and should have the encouragement which its importance deserved.

That, since the last meeting, the cause of medicine in the Philippines had been greatly advanced by the establishment in the city of Manila of the St. Paul's Hospital; that during the year Bishop Brent, of the Episcopal Church, had completed the necessary arrangements for establishing a general hospital; the Methodists had opened a dispensary, and soon hoped to have a maternity hospital in operation; the navy had completed a modern hospital at Cañacao, in Cavite, and the army had completed another at Fort William McKinley. The Government maintains a sanatorium in the mountains of Benguet, and dispensaries were operated either by church organizations or by the Bureau of

Health, at Cebú, Dumaguete, Cervantes, Laoag, and many other places throughout the provinces; that $5,000 worth of medicines had been sent by the Bureau of Health to remote portions of the islands for the relief of the indigent poor; that dispensaries were now operated at seven health stations in the city of Manila; that St. Paul's Hospital had surgical, medical, and dental dispensaries, and various other church organizations gave out patient relief.

He stated that while it was true that the facilities above mentioned showed great progress, it was also true that Manila is still far behind other cities of the same size, and that a large hospital, with modern buildings and equipment, was urgently needed for the relief of the afflicted, and that if the new Philippine Medical School was to be started with any hope of success, a hospital with teaching facilities, where practical medicine might be learned, would be absolutely necessary; otherwise, theorists would be the graduates.

The Culion Leper Colony would soon be ready to receive patients, thus eliminating one of the most pressing and vexatious questions with which the Bureau of Health had to deal; that the San Lazaro hospitals, with leper, insane, cholera, smallpox, and plague departments, had added to its equipment and facilities, and was better prepared than ever to meet any emergency that might arise.

A few years ago the medical profession looked to its representatives in India for its research work on all tropical diseases, but that since the American occupation of these islands, a great change had taken place; that the names of our scientific men were frequently seen in American and European medical literature; that the medical world maintained an attitude of constant expectancy toward the medical men in the Philippine Islands—an expectancy which had not yet been disappointed; that, during the year, results had been achieved in the advancement of medical science which were not only of interest to the Philippines, but which were matters which had aroused interest and comment from medical men in all parts of the world; that among the foremost might be mentioned the experiments which had been conducted at the leper department of San Lazaro Hospital, in the treatment of leprosy with the *x*-ray. While the work had not been sufficiently extensive to justify a positive statement, yet it had been successful enough to offer a well-grounded hope that the medical profession could hold out some encouragement to sufferers from that loathsome disease, who, from remotest times, had made them exiles from society, and denied all earthly hope; that the results achieved at least demonstrated that it was possible to cure some cases of leprosy.

Another noteworthy achievement was the improvement, by Dr. R. P. Strong, in the preparation of cholera and plague vaccine. A paper by Dr. Wherry, on "Glanders and Its Prevention," had been pronounced in Europe to be the best that had yet appeared on that subject; and the paper on "Tropical Light," by Major Woodruff, of the United States Army, which had attracted so much attention in the medical and lay press, had first been read before the Manila Medical Society.

The American medical profession had been represented in these islands only about eight years; they had been strenuous years, full of discouragements and disappointments, but the record as written was one in which every American physician could take pride. Those who had not had the opportunity to compare results of the sanitary efforts in the cholera epidemic of 1902 with the present epidemic, results might not appear so real as to those who were brought into daily contact with those for whom they were working; that measures which provoked profound opposition in the former epidemic were accepted, and even asked for now.

In speaking of the association, he said that no organization was ever actuated by nobler motives or inspired by higher ideals; it only remained to live up to those principles. The people in the Philippines needed, more than they needed anything, the extension of medical knowledge and advancement of medical science; that the medical profession of the islands needed that elevation of standard, that aid promised by the enforcement of just medical laws, that promotion of friendly intercourse, and that guarding and protecting of material interests promised by the Constitution: the solution of the great problems of State medicine depended upon the enlightenment and direction of public opinion, to which the association had pledged itself; that it was their sacred duty to become more capable, more honorable, and more useful to the public in the cure of disease, and the prolonging and adding of comfort to life.

"Well might the code of ethics of the American Medical Association enjoin us to be mindful of the high character of our mission, and the responsibilities that the physician must incur in the discharge of his momentous duties. Well might that same code of ethics declare that every physician should identify himself with the organized body of his profession as represented in the community in which he resides, and strive to make his local organization an instrument for the cultivation of fellowship, the interchange of professional experience, and the advancement of medical knowledge and the maintenance of ethical standards the promotion of the welfare of the public. The field is large, the work is great, the duty imperative; therefore, in order that we might more fully meet our responsibilities, we should ignore differences of opinion, forget personalities, and all work together for the success of the cause to which we had dedicated our energies, our ambition, and our lives."

OUR LONDON LETTER.

(From Our Special Correspondent.)

OFFICIAL CONTROL OF CONSUMPTION—EPIDEMICS, VARIABILITY, AND PERSISTENCY—DOUBLE OVARIAN CANCER—PYOSALPINX—SUNDAY FUND—UNIVERSITY COLLEGE HOSPITAL—MOUNT VERNON HOSPITAL—DEATH OF DR. G. H. PEARCE.

London, March 23, 1906.

The Local Government Board for Scotland issued on the 10th inst. an important circular to the local authorities on the administrative control of consumption, and on the 20th this action of the board was strongly commended as an example for us at the annual meeting of the National Society for the prevention of phthisis. The Scottish Board opens its circular by asserting that pulmonary phthisis is an infectious disease within the meaning of the Public Health Act, and, accordingly, that the sections relating to other infectious diseases are equally applicable to consumption, which is spread almost entirely by matter coughed up and spat out by persons suffering from the active and developed form. The board therefore recommend that the local authorities should see that disinfection is thoroughly carried out at frequent intervals in the homes of patients, in workshops, or wherever consumptives are employed, the process of disinfection not being left to the friends or fellow-workmen. The local authorities are further recommended to endeavor to have such disinfection carried out in places of public resort and to deal with the practice of spitting by patients. The board deals with a number of other questions concerned with prevention, and even treatment, including sanatoriums, hospitals, dispensaries, medical examinations at these, condition and accommodation of homes of patients, laundry matters, distribution of printed information, arrangements, expert examinations of sputum, blood, discharges, etc.; in fact, all matters concerning the control of phthisis. The authorities are reminded, in conclusion, that all such direct measures must be supplemented by the most thorough general sanitation throughout their districts. An appendix to the board's circular consists of the address on completer organization against tuberculosis delivered at the Paris Congress by Dr. R. W. Philip. Altogether the circular is a remarkable public document, and many are hoping the English Board will follow suit.

Dr. W. H. Hamer took for the subject of his Milroy lectures at the College of Physicians "Epidemic Disease in England—the Evidence of Variability and of Persistency of Type." The three lectures abounded in suggestions and statements which will give rise to reconsideration of some points. In regard to unstable diseases he referred to the possibility that apparent change of type may result from interplay between the organism and its environment. As to disease species, where is the line to be drawn? In dealing with bacteria, are differences of color reaction, fermenting of sugars, clotting of milk, liquifying gelatin, and killing of animals to be regarded as specific? No organisms present more instructive phenomena than the colon group. At one end *Bacillus coli* and its relations, at the other, *Bacillus typhosus* with various "strains," and between the extremes the organisms of dysentery, hog cholera, paratyphoid fever, and bacilli associated with meat poisoning.

The differentiation of species has been carried to such a degree by some that the least variation has been held to mark a distinction, and Dr. Hamer evidently does not follow them. He pointed out the unsatisfactory nature of conclusions adopted under laboratory conditions. The distinction of bacilli by their behavior as "polysaccharine factors" has called up their endowment with various enzmes to the confusion of observers who have not followed the literature closely, and it is pretty clear that Dr. Hamer has felt dissatisfaction with views advanced rather positively and is able to subject them to wholesome criticism. He said that the bacteriologist who claims that the most minute differences distinguish species has to reckon with the fact that the more numerous the species, the greater must have the power to vary throughout long ages, and he would consider that the question is rather one as to the number of stable forms. It is possible a particular organism occupying the attention of a bacteriologist may be a mere subparasite, capable of living symbol-

ically with the parasite-in-chief. Why should not, for example, the influenza organism sometimes live with Pfeiffer's bacillus, at another with micrococcus catarrhalis, and so on? Dr. Hamer suggested that a particular organism might conceivably cause more than one disease by being introduced by different intermediary hosts; also distinct diseases might result when the organism was accompanied by different enzymes or subparasites. With the latter hypothesis the occurrence of mild cases of typhus or influenza during interepidemic periods would fit in. The lecturer suggested that we may have concentrated too much attention on particular links in the chain of parasitism—studied organisms under laboratory conditions, and held disease to be bound up with them, forgetting the parasite might be one of a series, and that it might be replaced in that series by another, and then, for the time being and in that locality, have no further concern with disease. In conclusion he said: "The records of epidemics suggest that some such explanation must be looked for to reconcile the extraordinary persistency of disease types with the no less remarkable variability of the organisms to which the bacteriologist attaches importance as causes of disease."

The Gynecological Society at a special meeting on the 8th determined to discontinue its examination of nurses in view of the probable amalgamation of London medical societies. An alteration of the articles of association was also confirmed as to the filling up of vacancies among the officials.

At the ordinary meeting Dr. Jellett showed specimens of (a) advanced carcinoma of both ovaries; (b) double pyosalpinx associated with the presence of a four months' extrauterine fetus. In the former on exploratory incision the mass previously felt was found to consist of two separate pelvic tumors. The opening was enlarged by a transverse incision through the left rectus to the left superior iliac spine. The left tumor did not give much trouble, but the right was removed with difficulty on account of adhesions. An abscess was found between the tumors and so much infiltration of the ligaments that the uterus was also removed. Four months after leaving hospital the patient returned. Then the rectum was surrounded by a hard mass. But she has since gained weight and seems well.

In the second case on opening the abdomen Dr. Jellett found the right tube enlarged to the size of a sausage, distended with pus, and bound up with the ovary. The skeleton of the fetus projected from the ampulla. Ovary and tube removed. The left tube was also distended with pus, and therefore removed. The patient left hospital in three weeks and three months later was well.

The propriety of operating in such advanced case was naturally referred to in the discussion, and all the speakers considered the operations justifiable. Indeed, the results seem to show that.

Dr. C. H. F. Routh said no one who understood his work could have done otherwise in the first case, which displayed the finest skill and technique. If a patient was certain to die without an operation, it should always be postponed. He had seen hopeless cases recover, one where five members of the hospital staff considered the case inoperable.

Dr. Macnaughton-Jones said no doubt operation was justifiable, and he showed specimens of cancerous ovaries he had removed in such circumstances. He added that many carcinomatous and sarcomatous ovaries gave so little pain that nothing serious was suspected until operation seemed called for, and sometimes malignancy was only discovered at the operation.

Dr. Ryall said the danger of peritoneal infection was not so great as supposed; much less breaking into malignant growths in other organs.

The President, Mr. Bowerman Jessett, said he knew several cases in which the patients were practically dying who had been operated on and lived for years afterwards. It was absurd not to give a patient *in extremis* the chances of life. Sixteen years ago, at the express desire of a patient, he removed the whole breast, the pectoral muscles, and cleaned out the axilla, and she is now alive and well.

Dr. Jellett, in reply, said the transverse incision was made after the exploratory; it was the only time he had found it necessary. He could not retract the walls enough to get round the tumor, so he thought the transverse best. It healed well, in spite of infection from the pus in the pelvis. He was glad to find the opinion unanimous that the operation was justifiable and advisable.

At a special meeting of the Council of the Hospital Sunday Fund it was resolved to apply for a Royal Charter. Though the fund has been working since 1872, it has no definite constitution. It has been acting so far on the rules framed thirty-four years ago. It has no legal power to make by-laws or to give votes to the most generous supporters, say to Mr. George Herring, who has been contributing some £12,000 a year. The fund has increased from £27,000 to £78,000, and it seems time a definite constitution should be provided.

Yesterday the annual meeting of University College Hospital was held, when the report stated that the new building erected through the munificence of the late Sir J. B. Maple was complete and in full working order, with the exception of only one ward of twenty-four beds, the total number of beds available now being 277. But the treasurer reported a considerable indebtedness, and that unless liberal support were forthcoming it might become necessary to close some of the wards. The rateable valuation had been raised from £323 to £1,500, and, though donations had increased, there was a falling off of subscriptions.

Mount Vernon Hospital's annual meeting was held yesterday. The committee's report spoke of disparity between income and expenditure. It appeared there were 110 empty beds and 300 accepted candidates waiting for admission, but the committee had not funds at their disposal to admit more than a fraction of them. It looks as if this committee, with their separate hospitals at Hampstead and Northwood, had undertaken more than they can accomplish. It is not so long since they were in difficulties about meeting their rates. That should have been a warning not to launch out into too great expenditure.

Dr. George Heneage Pearce, aged 42, assistant medical officer of Humberstone Asylum, met with his death on Saturday when riding a motor bicycle. Evidence was given at the inquest that as he approached a farmer's cart he suddenly looked behind him, whereupon his machine swerved and came into collision with the cart, the shaft of which struck the doctor in the chest, and he died before reaching hospital. Death was attributed to shock. It was said that had he not looked behind the cycle would not have swerved, which statement seems to accentuate the perils of cycling.

PROFESSIONAL TREATMENT FOR INSOMNIA.

To the Editor of the Medical Record:

Sir:—Dr. John V. Shoemaker gives the readers of a recent issue of the *Saturday Evening Post* some good suggestions as to "how to get to sleep." He sees fit, however, to give the medical profession a resounding slap. Twice in the article referred to he warns his readers of the sad results of consulting a physician for insomnia. In the first instance the medical man has nothing to suggest but "a little whiskey before retiring"; in the other he gives the patient "one sleep-producing drug or another."

A considerable knowledge of the drug business leads me to the belief that the general use of drugs by sufferers from sleeplessness is usually due to a *failure* to consult the medical attendant. If the medical profession is sometimes guilty of prescribing sleep-producing drugs where other measures would be more appropriate it would be nice in Dr. Shoemaker to lecture his medical brothers on the subject rather than the public. George S. Wright, M.D.

Friday Harbor, Wash.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 5, 1906.

The Mental Symptoms of Cerebral Tumor.—P. C. Knapp analyzes the histories of 104 cases with reference to this point. Mental disturbances sufficient to attract attention were present in seventy-nine. For various reasons the author excludes fifteen of these and considers only sixty-four cases, in which mental symptoms were found in fifty-eight. Slight changes in this respect may naturally escape observation. Grouping the cases according to the nature of the symptoms, it is noted that thirty-one presented the recognized type of mental failure and dullness in varying degree. In seven there was noticeable mental confusion, lack of memory, irrelevant speech, somnolence, stupidity, etc. In fifteen the mental impairment went on to actual delirium, three becoming wildly maniacal and several others requiring restraint. Actual hallucinations were occasionally noted. Neurasthenic and hysterical states were occasionally observed in the earlier stages of the disease. In two cases there were definite hallucinations of persecution. There were no striking differences as to the period of the disease at which the different types of mental disturbance developed. Five of the six cases of the frontal lobe exhibited mental disturbance. Of four tumors in the Rolandic region, two were mentally dull early, one later, and the fourth developed delusions of persecution. Of two parietal cases one presented early neurasthenic symptoms and the other became dull and stupid toward the close. Of six temporal cases, two

were dull, two confused, one delirious, and one presented an appearance typical of general paralysis. Of three collosal growths, all were confused, delirious, violent, and demented. Of nine cases of growth in the optico-striate region, seven were dull. Two cases of growth in the corpora quadrigemina were dull early, while a third showed early mental impairment with delusions of persecution. A case of tumor of the pons was dull. Five out of seven cerebellar tumors were mentally dull, but only one showed this mental failure early. The sixth was delirious. In the seventh case no mental symptoms were noted, but she had headaches with intense vertigo, aggravated by any effort, so that mental symptoms may well have been overlooked. One tumor of the hypophysis showed mental confusion early in the disease. The second was delirious toward the close. Of the seven tumors at the base of the brain, five were in the anterior fossa. Of these, one became dull early, three showed mental confusion later in the disease, and a fifth was delirious, showing mental disturbances early. One tumor in the middle fossa became delirious later in the disease. In only one case of a tumor in the posterior fossa, a growth of the cerebellopontine angle, not involving the brain deeply, there were no noteworthy mental symptoms.

The Operation for Cataract.—F. E. Cheney describes his method of operating, going into full details, which cannot be given here. For a local anesthetic he prefers a 1 per cent. solution of holocaine to cocaine. He admits that as to asepsis the ophthalmic surgeon labors under decided disadvantages. The normal salt solution undoubtedly goes farther than the usual germicides so far as safety is concerned. Great stress is laid upon the sterilization of instruments, which should be used with the greatest care when we are passing them into the anterior chamber, so that they come as little as possible in contact with the outer surface of the globe. For the same reason the fewer instruments that enter the anterior chamber, the less chance of infection. To remove and reenter an instrument is always to be avoided unless absolutely necessary. He notes that a source of infection in certain cases is probably the fluids, aqueous, lacrymal, etc., collecting in the lower culde-sac after they have washed the conjunctiva pretty thoroughly and are likely to be well laden with bacteria. Unless such fluid is removed by occasional sponging, the ends of the corneal wound are sometimes well bathed in it when the eye is rotated downward. Especially is it important to see that this space is well dried before removing the speculum, as the closing of the lids may force this collection over the entire length of the incision. He always uses atropine after operating. It does not seem, according to his experience, to increase the danger of prolapse, and he regards it as certainly an advantage to obtain mydriasis as early as possible.

New York Medical Journal, March 31, 1906.

The Prognosis of Postoperative Femoral Phlebitis.—B. R. Schenck reviews the statistics on this question as illustrated by the personal reports of various operators. He has previously reported forty-eight personal cases and has been able to obtain the later histories of twenty-nine of these patients. These twenty-nine he divides into three groups: (1) Those having symptoms for a period of four months or less and subsequently no trouble, of whom there were eight; (2) those having symptoms for about a year and thereafter no disturbance, of whom there were two; (3) those who have had symptoms ever since the attack, of whom there were nineteen. In none of these cases are the symptoms so severe as to cause any very marked disability. Practically all of the patients state that the swelling is slight and the pain present only after walking or being on the feet more than usual. The author concludes: (1) That all patients have symptoms for a period varying from two to four months; (2) that, if the symptoms persist longer than six months (by which time the collateral circulation is probably as completely established as it ever will be), there is small chance that they will ever disappear; (3) that in about 65 per cent. of all cases there is never complete freedom from attacks of pain and swelling.

Conjugate Lateral Deviation to the Left.—One case is reported by J. H. Claiborne. The patient was a German of 57 years, with a syphilitic history. The salient features of the case, as stated by the author, were the conjugate lateral paralysis with deviation to the left, fugacious left hemianesthesia and hemiplegia, the location by exclusion of the lesion at the nucleus of the right sixth nerve, the absence of hemianopsia, the obvious predominance of the paralysis of the external rectus as opposed to the internal rectus, and the retention of normal convergence.

Myelitis Complicating Pregnancy.—After some observations on this complication as reflected in the teachings of various writers on obstetrics, J. T. Schell gives the history of a woman in her second pregnancy, with whom all went well up to near the end of term, when after a day of unusual exertion in very inclement weather she had the impression of having "taken cold." She had a slight chill and general muscular soreness, especially in the lumbar region and down the thigh. Temperature at this time was 102°. Next day she was better, but on the day following, when attempting to get out of bed, found she had lost control of her left leg and in about twelve hours of the right also. Knee jerk was completely lost on both sides. Sensation to touch was normal, with no anesthesia. Incontinence of urine was present and lasted two days. Bowels were not affected. The fever fell to normal on the sixth day, tenderness in the back and legs rapidly disappeared but the paraplegia remained as before. She was delivered at full term without incident. At time of writing she had regained slight motion in the right leg, but was still unable to stand. The diagnosis of myelitis was agreed to by the consultant, who regarded the attack as due rather to exposure than to the toxemia of pregnancy.

The Chemical Composition of Medicinal Plants.—E. C. Hill gives some interesting facts about the chemistry of the plants commonly used in medical practice. According to his count, there are indexed in the eighth decennial revision of the Pharmacopœia of the United States 157 medicinal plants. Although the present revision shows a commendable reduction in the total number of titles, this elision might be carried, he thinks, much further with benefit to all concerned. For example, he finds herein 16 plants which owe practically all their value to contained tannic acid. Why should we not restrict these preparations to a much smaller number, or use tannin itself? Given with milk, it is tasteless, and is liberated in the intestines, where its action is desired in most instances. By using fewer drugs we should learn to employ them with the confidence and certainty with which the surgeon manipulates his instruments.

Journal of the American Medical Association, April 7, 1905.

Gastric Cancer.—William J. Mayo points out that there is no medical side to cancer of the stomach, and reviews the literature, showing what enormous strides have been taken in gastric surgery of late years. He reviews the statistics of several leading surgeons as well as his own, and shows that not only in the direct mortality of the operation, but also in its later results, it compares favorably with the surgery of cancer of other parts of the body. The only way in which an early diagnosis can be made is by exploratory incision, but clinical symptoms, especially if associated with a history of old or recent ulceration, may arouse suspicion and justify exploration. He gives in detail his steps in performing the radical operation for cancer of the stomach, and remarks that the results of palliative operations are relatively unsatisfactory, the mortality being comparatively high and the average prolongation of life not very great. In 140 of his cases of gastroenterostomy the mortality was 15 per cent., and the average prolongation of life so far as known was less than five months. The figures given by Kronlein and Mikulicz are even worse. The operation merely prolongs a chronic invalidism by a few hopeless, weary months. For cancerous obstruction of the cardiac orifice, however, gastrostomy is the only resource, and is frequently demanded by the patient. He has had eighteen cases with three deaths, a mortality of 16 per cent. The duration of life was about the same as after gastroenterostomy. Of explorations with discovery of hopeless gastric cancer he had seventy-two, with one death in the hospital. The average stay of such patients in the hospital is less than five days, the deep wounds being closed with catgut, and the strong aponeurotic structures braced with buried mattress sutures of linen, silk, or silver. The patients are thus enabled to get about at once and spend the remainder of their lives with their families. In conclusion, Mayo urges on the profession the merits of the radical operation in suitable cases of gastric cancer. The article is elaborately illustrated, showing the steps of the operation.

Appendicitis.—The reasons why early operation will never become the universal practice—the unlikeliness of sufficiently prompt diagnosis and the necessity of gaining consent—are pointed out by O. B. Campbell, and the

importance of proper preliminary medical treatment is emphasized. He objects to the use of purgatives and believes the best results will follow measures directed to the arrest of peristalsis by abstinence from food and drink, rest in bed, the only nourishment being given by the rectum, administration of morphine to allay pain, and the placing of the patient in the improved Fowler position, that is, with the head and left side of the bed elevated. In abscess cases he prefers an incision at the outer border of the right rectus to one immediately over the abscess, and advises closing the abdominal wound and securing drainage through a flank incision. In case of beginning diffuse peritonitis he thinks the Ochsner treatment is generally best. His views are summed up in substance as follows: In incipient appendicitis, before the patient is in the surgeon's hands, all food and drink, except by the rectum, should be withheld. Every patient should be informed of the advantages of early operation. Removal of the appendix or closure of an opening in the cecum should be done in abscess cases when possible without additional risk to life. Mere drainage in every abscess case is to be condemned as non-surgical. Operation during a progressive diffuse peritonitis will be attended with a higher mortality than the procedure here recommended. If the internist could direct his treatment toward the protection of the peritoneum in appendicitis until he can transfer the case to the surgeon, the mortality, Campbell thinks, would be greatly lessened. The adoption of the more rational (Ochsner) method of dealing with diffuse peritonitis will convert a large percentage of these cases into cases of circumscribed peritonitis, when they can be rightly classed as large abscess cases and have the same mortality rate as such.

An Operation for Pyosalpinx.—W. D. Kelly describes the operation for pyosalpinx, which he has performed for a number of years, as follows: The patient is placed in the Trendelenburg position; the bowels, relieved from adhesions if necessary, are pushed back, and the field of operation is walled off with one or two large strips of gauze. Bleeding, if any, should be sought for, and the finger is invaginated between the ligament and the mass and the tube partially freed at the distal end. The index finger is then forced between the broad ligament and the tumor. A cutting needle, half curved, with No. 3 pyoktanin catgut, is passed between the mass and the broad ligament on to the finger, and the broad ligament is tied off. Scissors are used to sever the tissue between the broad ligament and tube. The finger is still further advanced and an overthrow provisional suture, which usually includes the ovarian artery, is taken in the broad ligament. The mass is further separated by advancement of the finger; application of another provisional suture, and the severing of the mass from the broad ligament with the scissors, a little at a time. Immediately on severing the tissue the provisional overthrow suture is tightened, thus preventing hemorrhage. In most cases it is well to put in the provisional Billroth suture before severing the artery. The finger is still further advanced toward the uterus, and the broad ligament is severed as before described, following the provisional suture until the horn of the uterus is reached. The provisional suture is placed in the uterus, an elliptical incision is made, and the tube is removed from the uterus and the suture tightened. Another suture, if necessary, is imbedded in the uterus and tied. The uterus is then grasped with the hand and elevated, if possible. If this elevation is not possible, an attempt is made to separate the adhesions directly behind the uterus, and in this way gradually to shell out the mass from before backward. It may be necessary to tie off some omentum or bands of adhesion. Kelly claims that this operation is almost bloodless and can be performed without the use of ligatures or artery forceps. Drainage is almost never necessary and no counter openings should be made.

The Blood Plates.—G. T. Kemp, H. Calhoun, and C. E. Harris give the results of their enumeration of the blood plates in various conditions of altitude, disease, etc. The various methods and fluids that have been employed are thoroughly discussed and criticised, the one employed by the authors being a solution of formalin in a 1 per cent. solution of sodium chloride, in the proportion of 1 to 15, and colored as desired with methyl green or violet. The ratios determined by them in winter in human blood were almost invariably higher and more constant than those obtained in summer. The same is true of those at high altitudes, but here the red cells were also increased. They review the results of various authorities in pathological conditions, and from the mass of evidence believe that three important generalizations can be culled. The first relates to acute infectious fevers; during their course the number of the blood plates is usually subnormal or normal, but if the fever breaks by crisis it is accompanied by a rapid and striking rise in the number of blood plates. Most observers agree to this, and without exception in the case of typhoid. The second generalization concerns the anemias. There is a remarkable agreement in the belief that the plates are not diminished in the secondary anemias; indeed, they are reported increased in most cases. In pernicious anemia, on the other hand, they are always greatly diminished, and their count is, therefore, of great importance in the diagnosis and prognosis of the case. Lastly, in purpura hemorrhagica the blood plates are enormously diminished in number, and the few that are found are often of large size. This scarcity of the blood plates and slowness of the blood to clot are given by Hayem as the pathognomonic and constant signs of the disease. The authors believe that further investigations of the blood plates, in fevers especially, would lead to valuable results, besides being of use for the diagnosis and prognosis of the cases under observation.

The Lancet, March 24, 1906.

Mycosis Fungoides Successfully Treated by the X-Rays.—The patient of G. G. Taylor was a man of forty-seven years, with numerous tumors scattered over his back, the largest the size of a duck's egg. Large areas of the adjacent skin showed the premycotic condition, which in this case was of the erythematous type, one large disk being very distinct. One of the smaller nodules was removed for the purposes of histological examination. On cutting into the tumor it appeared to the naked eye as a round mass, much denser and firmer than the surrounding tissue and sharply defined from it. Microscopical examination showed a round mass of densely packed cells in the corium. The cells consisted of connective-tissue cells of various shapes, numerous small round cells, and a few plasma cells. No mast cells were found. In some parts the cells were less deeply stained and were crenated in appearance; granular débris was scattered between them. In some parts of the specimen, especially around the periphery, the cells were arranged in columns. Outside the main mass foci of cells were scattered through the corium. The epidermis was thinned and its interpapillary processes flattened out; there was intercellular edema. Exposures of ten minutes' duration each were employed twice a week at a distance of nine inches from the anticathode, 0.5 Holzknecht's units being administered at each sitting with rays of penetration 7 on Benoist's scale. In all fifteen exposures were given. The facility with which the tumors yielded to the treatment was remarkable, since improvement was noticed after the third sitting, and they were completely level with the skin before the hair fell from the adjacent parts of the back.

The Therapeutic Effects of Mercury in a Case of Tuberculous Meningitis; Recovery.—The patient of Whitcombe-Brown was a girl one year old. The usual symptoms of tuberculous meningitis developed. On the fourth day inunctions of the Ung. Hydrargyri were commenced, while the perchloride and the iodide and bromide of potassium was given by the mouth. The symptoms continued for four days, when a marked improvement was noted. From this time convalescence was slow but steady, and in six weeks from the first appearance of symptoms all of the nervous and muscular disturbances were at an end. The report of the case was made at this time. The inunctions were being continued, applied at the nape of the neck or between the shoulders, a piece as large as a filbert nut being rubbed in once a day. For the first fortnight this was applied twice a day. A mixture, two and a half minims of perchloride of mercury, one grain of iodide of potassium, and two grains of bromide of potassium, with syrup and water every four hours, was alternated with the syrup of iodide of iron. The patient was on a full milk diet with beef tea and cod-liver oil emulsion. Lumbar puncture was impossible, as the parents would not consent. As there were difficulties in connection with obtaining an opsonic curve, tuberculin was not tried. There seems, however, little doubt that this was a case of tuberculous meningitis. Three medical men, each without previous knowledge of the opinion expressed by the others, at once gave the same diagnosis.

Post-Traumatic Hemorrhage from the Superior Longitudinal Sinus Without Fracture of the Skull.—An interesting case is reported by E. F. Buzzard and J. Cunning. The patient, a man of twenty-five years, fell on the back of his head, inflicting a scalp wound. Two weeks later he reported that he had had increasing headache since the accident. It was not localized, no eye

symptoms were present, and no paralysis. The abdominal reflex on the left side was absent, the left knee jerk was more brisk than the right, and an extensor response followed stimulation of the sole of the left foot. A tentative diagnosis of intracranial abscess was made and the patient urged to enter the hospital. He did not come for two days, having had meantime some vomiting and some paresis of the left hand and left leg. On admission, symptoms of intracranial lesion were much more pronounced, and two days later he showed left hemiplegia, hemianesthesia, and hemianopsia, but no optic neuritis. Trephining was done over the posterior portion of the fissure of Rolando and a large clot was found beneath the dura. A portion of the clot gave evidence of having been present for several days. The middle meningeal artery was suspected as the source of the bleeding, but the progress of the operation seemed to point to the superior longitudinal fissure as the source of the fresh blood which appeared. The superior longitudinal sinus was exposed and found to be bleeding freely into the subdural cavity. The dura was split up to the bleeding point, forceps applied, and gauze packed around them. The patient's bad condition made saline infusion necessary. Next day the patient was conscious but had considerable pain. Other symptoms were as before. A day or two later the forceps and gauze plugs were removed without incident. Two weeks after operation the patient was allowed up, and two weeks later went to a convalescent home. He exhibited at the time slight weakness and clumsiness in the left arm and hand. Complete recovery ensued. The authors have not been able to find the records of any similar case of hemorrhage from the superior longitudinal sinus in the absence of skull fracture.

British Medical Journal, March 24, 1906.

Intracranial Hemorrhage in the Newborn.—One case is reported by J. C. Turnbull. The child was delivered by forceps under very moderate traction. It cried well and presented only a slight ecchymosis over the left eyebrow. At the end of twenty-four hours it gave a peculiar cry and soon went into tonic convulsions, somewhat controlled by cold to the head, but proving fatal in forty-five hours after birth. Autopsy showed a hemorrhage into the subdural space, probably from rupture of vessels in the pia over the lower aspect of the left hemisphere. The pressure of the effused blood on the veins of Galer and the cranial sinuses had produced edema of the brain and internal hydrocephalus. The author believes that the hemorrhage cannot be accounted for by direct injury to the head from either forceps or pelvic bones. In his opinion the high cerebral blood pressure which must result from rigid contraction of the uterus on the placenta and soft parts is a much more important factor and indicates delivery before the uterus is fatigued, as a prophylactic measure. He believes it would be extremely difficult to locate and ligature a ruptured vessel if craniotomy were performed, as has been suggested.

Ascaris Lumbricoides and Appendicitis.—F. E. Anley summarizes a series of cases which have come under his notice in which patients have been attacked with the usual symptoms of an appendicitis, the same subsiding with the passage of a round worm. The author observes that the habit of the ascaris of inserting itself into apertures and ring-like bodies is well known, and it has seemed to him that an inflammation may be set up by the worm attempting to enter the appendix, sufficient to cause blocking of the lumen, leading to a resultant catarrhal appendicitis; or the worm may actually obtain a partial entrance if not more.

Traumatic Pneumonia.—H. L. E. Wilks calls attention to the fact that much damage may be done to lung tissue without any cutaneous bruising, instancing the case of a boy brought to the hospital with symptoms of internal hemorrhage. No positive history of an accident could be obtained, though he was found in the road and it was possible that a wheel had passed over him. The boy died and autopsy showed a severe laceration of one lung, a large piece of pulmonary tissue lying free in the pleural cavity. There was no fractured rib and hardly any external bruising was visible. He refers to another case—that of a man who had been upset from an automobile. He had local tenderness over one rib, a distinct pleural friction sound, but no pyrexia and no extension of the trouble. The author considers that under such conditions the pneumococcus does not take on its growth in the affected area.

Lumbar Puncture in Puerperal Eclampsia.—Two case histories are given by F. Proud. The seizures in such cases may be due to either toxemia or pressure on the cerebral centers. Acting on the latter theory, puncture was done in both the cases referred to. In Case 1 the usual remedies had been tried without avail, so a puncture was made in the third lumbar interspace and fluid allowed to drop rapidly for some minutes. Recovery ensued. A similar happy result occurred in Case 2. Here the fluid gushed from the needle, it evidently being under pressure. About half an ounce escaped.

Berliner klinische Wochenschrift, March 19, 1906.

The Occurrence and Etiology of Unilateral Clubbed Fingers.—Bernhardt reports a case which is similar to those recently published by Berent and Grödel. The patient was a man of sixty-two years who had had syphilis thirty-eight years previously. On *x*-ray examination he was found to have an aneurysm of the ascending aorta and arch of the aorta, the condition being accompanied by more or less typical symptoms of pain and loss of function. While the right upper arm and forearm were smaller than the corresponding portions of the left arm, the right wrist and entire hand were considerably larger, the finges were clubbed, and presented well-marked claw nails. The author agrees with Berent that the changes in these osteoarthropathies are the result of neuritic processes rather than of simple congestion or the action of toxins produced through congestive or catarrhal processes in the lungs.

An Improvement in Mett's Method of Determining the Digestive Power of Fluids.—Meier, in discussing this method of estimating the digestive power of gastric juice and similar secretions, points out several sources of error in the technique usually employed. The procedure consists in drawing egg albumen into capillary tubes which are heated until coagulation of the albumen takes place. The tubes are then cut into short pieces and one of these is placed in a test tube of the fluid whose digestive power is to be estimated. At the end of twenty-four or more hours the activity of the digestive process is shown by the length of the column of albumen which has been digested out of the capillary tube. Meier says that in preparing the tubes it is difficult to avoid the occurrence of minute air bubbles in the column of albumen, and that these, if present, give rise to a very considerable source of error in the digestion. Again, in cutting the tubes into short lengths all of those must be discarded in which the line of fracture is not clean cut and at right angles to the long axis. Tubes which are not completely filled with albumen, or from which a small portion of albumen projects, also yield inaccurate results. The measurement of the length of the digested column is also a frequent source of error, and the author describes a special piece of apparatus by means of which accurate measurements to one-eighth of a millimeter my be made. Finally, it is stated that if the tubes are used as is ordinarily done by allowing them to stand vertically in a test tube of the digestive fluid, to obtain accurate results it is necessary to disregard the digestion which takes place at the lower end of the tube, because of various disturbing factors which modify the process in this situation. Meier prefers to have the tubes lie horizontally, under which conditions the digestion which takes place at each end may be taken into account, and he describes a special form of receptacle in which the test may be carried out in this way with the expenditure of a minimum amount of the fluid to be tested.

The Treatment of Hemeralopia with Liver.—Sicherer reports remarkable results in the treatment of hemeralopia by means of the administration of liver, and cites the following case. The patient was a forty-five-year-old cab driver, whose vision was perfect in the daytime, but failed rapidly with the onset of twilight, so that he could hardly see his horse's head and had to inquire of passers-by in order to inform himself of the numbers of the houses. On this account he was finally compelled to give up his work and seek medical aid. The patient was ordered to eat 300 to 400 grams daily of cooked liver, and at the end of four days marked improvement had resulted, followed by complete cure at the end of a week.

New Tuberculosis Cure.—A dispatch from Tokio to the *Daily Telegraph* says that Dr. Ishigami of that city has announced the result of a year's experiments with an antitoxin against tuberculosis which he has discovered, and which, he says, unlike other antitoxins, does not result in a rise in the patient's temperature. Dr. Ishigami asserts that the antitoxin has resulted in cures on an average of one-third of the patients experimented upon. The treatment, however, he says, is not applicable in advanced cases.

Book Reviews.

The Edinburgh Stereoscopic Atlas of Anatomy. Prepared under the auspices of the Department of Anatomy of the University of Edinburgh by Professor J. R. Cunningham, M.D., D.S.C., LL.D., D.C.L. Edited by David Waterston, M.A., M.D., F.R.C.S.E., F.R.S.E., Lecturer and Senior Demonstrator in the Department of Anatomy, Edinburgh University. Section II. New York: Imperial Publishing Co., No. 27 East Twenty-second street.

The principle of stereophotography has already been made use of in works in several departments of medicine with such excellent results that it is rather remarkable that this method of securing illustrations has not been more widely applied. The subject of anatomy particularly lends itself so admirably to depiction by this means that the utility of such a collection of photographs as the present can hardly be exaggerated. The section under consideration is devoted to the abdomen, with its contents, excepting the female genitalia, and comprises four plates on the abdominal wall, six on the inguinal region, seven on the abdominal cavity, twenty-one on the viscera, one on the abdominal aorta, eight on the pelvis, and three on the bladder. The dissections have been made with a degree of judgment and technical skill entirely beyond the average student's ability, and as the method of formative hardening *in situ* has been employed, the topographical relationships are preserved with absolute accuracy. The structures are identified by small numbered pointers affixed to the specimen, and each pair of prints is mounted on a card bearing the necessary key and a few lines of letter press presenting a concise summary of the most important features represented. A well-made stereoscope accompanies the plates, and if the sections that are to follow bear out the promise of this one both editors and publishers are to be congratulated on having created a work that must surely prove of the greatest service to students, practitioners, and surgeons.

Clinical Obstetrics. By Robert Jardine, M.D., Edinburgh; M.R.C.S., England; F.F.P.S., Glasgow; F.R.S., Edinburgh. Professor of Midwifery in St. Mungo's College, Glasgow; Senior Physician to the Glasgow Maternity Hospital; Examiner in Midwifery to the Scotch Conjoint Board; formerly Examiner in Midwifery to the University of Glasgow; late President of the Glasgow Obstetrical and Gynecological Society, etc., etc. With ninety-six illustrations and a colored plate. Second Edition. New York: Rebman Company, 1905.

In this treatise on clinical obstetrics the author discusses pregnancy, labor, and the puerperal state, together with the various complications that can occur in these conditions. Right from the start the book is personal, practical, and thorough; merely academic discussions are rigidly excluded. The basis of the book is the personal experience of the author; he tells us what he himself has done, why he did it, what results ensued, and what he would do again under similar circumstances. We would draw particular attention to the author's sections on heart disease as a complication of pregnancy and labor; to the treatment of eclampsia; and to the chapters on the hemorrhages of pregnancy, and post-partum hemorrhage. This book will appeal to the practitioner, as it contains just the advice and help that he is apt to require; it mentions, and fairly faces, all the difficulties that are liable to be encountered in obstetrical practice; nothing is evaded, and the author states his failures as well as his successes. Throughout one feels that the book is written by one who has not only had unrivaled opportunities, but who also knows how to express clearly what he wishes to say, and to gain the confidence of the reader. This is a most useful book.

Sexual Neurasthenia (Nervous Exhaustion); Its Hygiene, Causes, Symptoms, and Treatment. With a chapter on Diet for the Nervous. By George M. Beard, A.M., M.D. Formerly Lecturer on Nervous Diseases in the University of the City of New York; Fellow of the New York Academy of Medicine, etc. Edited with notes and additions by A. D. Rockwell, A.M., M.D., Neurologist and Electrotherapeutist to the Flushing Hospital; formerly Professor of Electrotherapeutics to the New York Post-Graduate Medical School and Hospital; Fellow of the New York Academy of Medicine, etc. Sixth Edition, with formulas. New York: E. B. Treat & Co., 1905.

In this new edition of Beard and Rockwell's well-known work attention is drawn to the symptom of urinary incontinence in its relation to neurasthenia. In many cases this incontinence is the cause of the neurasthenic symptoms; and in some cases it is possible to bring about the disappearance of the neurasthenia if one can only succeed in relieving the incontinence with which it is associated. Dr. Rockwell has managed to effect this in some cases by the action of the isolated induction shock on the atonic perineal muscles; and a description of his method and technique forms the chief feature of the chapter which he has added to the book.

How to Become a Trained Nurse. A Manual of Information in Detail, with a complete list of the various training Schools for Nurses in the United States and Canada. Second Edition. Edited by Jane Hodson, Ex-Directress of Nurses, State Hospital, Fountain Springs, Pa.; Ex-Matron of the House of Relief, Hudson Street, New York; Graduate of the New York Hospital Training School. New York: William Abbatt, 1905.

This book can be divided into two parts; the first and larger part consists of a number of short chapters on various aspects of nursing and on subjects of interest to nurses. Among others there are chapters on private nursing, hospital nursing, nursing in private sanatoriums, district nursing, obstetric nursing, male nurses, etc. These chapters are by different writers, and consequently vary both in style and merit. The one that has impressed us the most favorably is the exceedingly sensible and practical article on "Private Sanitarium Employment," by Miss Alston, of New York. There is a chapter on "Some Eminent Nurses," giving sketches of the careers of Florence Nightingale, Alice Fisher, "Sister Dora," and Agnes Jones. The remainder of the book contains a list of the training schools for nurses in the United States and Canada, with such particulars as are likely to be useful to would-be nurses. This is the more important part of the book, and in it will be found an answer to many of the questions likely to arise in the minds of those desiring to become trained nurses but who know little or nothing of hospitals and training schools. There is also provided a list of denominational schools, schools for colored nurses, for men, and for attendants on the insane. Next is a list of questions asked of candidates for admission as probationers; and such candidates would do well to read this list before making application.

Movable Kidney. A Cause of Insanity, Headache, Neurasthenia, Insomnia, Mental Failure and other Disorders of the Nervous System. A Cause also of Dilatation of the Stomach. By C. W. Suckling, M.D., M.R.C.P., etc. London: H. K. Lewis, 1905.

As indicated by the title, the writer of this little book finds in displaced kidney the cause for many ills to which the human frame is heir. His enthusiasm leads him to make a number of forcible statements, among which may be cited the claim that "no man or woman should be sent to an asylum (for the insane) to-day without careful and repeated examination for dropped kidney." The work is based largely on the author's personal experiences and consists in great part of case records of patients who have been apparently freed from a large variety of symptoms by the restoration of a movable kidney to its normal resting place. Goelet's operation is preferred for this purpose and is described in an appendix. There are numerous illustrations and charts, including photographs of patients before and after operation; the good effects are marked even in their facial expressions of happiness and content.

Bodily Deformities. In a Series of Lectures by the late E. J. Chance, F.R.C.S., England; Edited by John Poland, F.R.C.S., England. Second Edition. In two Volumes, Volume I., London: Smith, Elder & Co., 1905.

This little book is interesting from the historical standpoint rather than from the technical, for it contains in amended form the lectures delivered by Dr. Chance at the old Hunterian School of Medicine, over fifty years ago, and first published in 1862. The lectures are presented by the present editor in their original form, a certain number of footnotes bringing the book in line with later research on this subject. The "nature, variety, and causes of bodily deformity" are dealt with in the first volume; the second was to include treatment, but has never been published. At the time when these lectures were first delivered, orthopedic surgery had just become established in England as a specialty, and the author's arguments with reference to the etiology of congenital deformities constitutes very interesting reading, despite the progress which has been made in this branch of medicine.

A Pocket Formulary By E. Quin Thornton, M.D., Assistant Professor of Materia Medica in the Jefferson Medical College, Philadelphia. New Seventh Edition, Revised. Philadelphia and New York: Lea Brothers & Co.

The present edition of this useful formulary brings its prescriptions into harmony with the requirements of the new United States Pharmacopeia. The little volume has also been subjected to emendations in other particulars, and can be commended to those whose needs lie in this direction.

Society Reports.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.

Eighteenth Semi-Annual Meeting, Held at St. Joseph, Mo., March 22 and 23, 1906.

DR. JOHN E. SUMMERS OF OMAHA, PRESIDENT.

Surgical Treatment of Goiter.—Dr. CHARLES H. MAYO of Rochester, Minn., read a paper with this title, which was based upon two hundred operations. He said that the neck was a field for specialism in surgery, while diseases of the thyroid gland were one of the numerous attractions. Accessory thyroids were usually but lost or unattached parts of the gland in lines of development. The statistics of myxedema following operation were unimportant in this country as yet, owing to the infrequency of the complete operation. Many cases of partial and even complete myxedema without operation were overlooked. Large cystic and encapsulated tumors within the glands could be enucleated to save useful gland substance. In Graves' disease one lobe and the isthmus should be removed, and if there was recurrence of symptoms, the lower part of the remaining lobe should be taken away. In the worst cases this should be done at the primary operation. Operation in this disease was no longer experimental. Both medical and serum therapy were still under discussion. Fearing malignancy, early operations were recommended in irregular and hard tumors. Transverse sections of the skin and platysma muscle, with muscle section of the omohyoid, sternothyroid, and hyoid as high as the thyroid cartilage, should be made to preserve intact their nerve supply in cases in which it was necessary to obtain greater space. More than one-half the operations performed upon the thyroid gland were those of expediency. It was therefore necessary that a low mortality rate accompany operations for goiter. During the last fifty years the mortality had been reduced from forty per cent. to a fraction of one per cent. In a total of over two hundred operations upon the gland, if the cases of exophthalmic goiter and malignancy were excluded, there was but one death.

Dr. L. L. MCARTHUR of Chicago said that Rogers of New York, within the last two months, had presented a method which was very promising in the treatment of exophthalmic goiter. He was led to his investigations in regard to this disease through the sufferings of his wife. When her condition became so severe that it seemed she was about to die, he became desperate enough to try some serum experiments. He accordingly made some emulsions of recently excised thyroid goiter of the exophthalmic type, and injected them into rabbits. From the rabbit he obtained a serum, one injection of which practically caused disappearance of all the symptoms of goiter in his wife. The profession of New York was extremely enthusiastic over the future of this line of treatment for severe types of exophthalmic goiter.

Dr. T. C. WITHERSPOON of St. Louis had had experience with 18 cases of typical exophthalmic goiter. He had operated upon this number of patients, and in each case, save one, he used local anesthesia. About five weeks ago he removed an exophthalmic goiter from a patient suffering at the same time from malignant disease of the breast. Her pulse, on an average, was 140. One week after removal she was in good condition. Her pulse dropped to 95. He used a general anesthetic (ether), and removed the breast radically, but within five hours thereafter her pulse was 170, although while on the table her condition was good. The amount of blood lost was small. There was no reason for the high pulse save the general anesthetic. After this time the pulse quickly dropped, and she recovered. His fear had always been the ill-effect of general anesthesia in these cases.

Dr. Mayo, in closing, said that Dr. Rogers had undoubtedly developed a cytolysin for the destruction of the thyroid. In working with normal thyroids Dr. Rogers had not been able to get any effect. This winter Dr. Mayo sent him seven exophthalmic glands with which to do his experimental work, because it was essential to use a diseased organ. He recently received a letter from Dr. Rogers, stating that he had removed the only exophthalmic goiter in New York the past winter. The serum treatment had to be worked out; while the results were favorable in twelve cases of Dr. Rogers in others no benefit had resulted.

Some Pathology of the Morphine Habit.—Dr. S. GROVER BURNETT of Kansas City, Mo., commended (1) the acute hyoscine poisoning method, attended by coma, delirium, and reactionary prostration of both mental and physical forces; (2) the abrupt disuse of the drug, as was enforced in jails, penal institutions, and asylums; (3) the rapid withdrawal of the drug during four to eight days; (4) the so-called slower reduction, requiring fourteen to twenty days. In his opinion, these methods could be applied only to selected cases. The author's reasoning for a delicate technique in treating the morphine habit was based upon an imperfect but an acceptable knowledge of the pathology as found post-mortem in three cases, one of which is here reported. In this case, that of a man, aged forty-five years, addicted several years, using hypodermically sixteen grains of the drug daily, and suffering severely, the patient manifested the typical general symptoms of the habitué. He did not take any food for a week before death. After a large injection, the quantity of which was unknown, he died in a few hours from typical morphine poisoning. Autopsy revealed fatty degeneration of the heart, muscles, liver, and kidney, pulmonary edema and venous congestion of the viscera; atrophy of the pancreas, replaced by fat; considerable edema of the brain. Microscopically, most of the cells of the central nervous system showed a marked absence of the normal amount of the chromatic substance. In the cells of the cord, medulla, cerebellum, and cerebrum these bodies were deficient in size and number, or entirely absent. In the medulla the chromatic bodies were retained by some cells, but they had undergone marked subdivision and the nuclei were shrunken and eccentric. The granular yellow pigment was increased in all the cells of the central nervous system.

His last forty patients, with one exception, had been physicians, members of physicians' families, or nurses. He said that many physicians addicted to the morphine habit would make habitués of their wives or others with whom their professional position allowed close association.

Dr. F. E. COULTER of Omaha said that in cases of morphine habit or drug addiction, it was very essential to have the hearty cooperation of patients to be successful in any line of treatment we might inaugurate. Every avenue should be put out of the way of a morphine habitué whereby he could get the drug. The patient should be placed in an institution where it would be pleasant and where he would not feel that he was in prison. His associates should be congenial. The nurse should be satisfactory to patient. Personally, he employed what was known as the physiological method in treating these patients.

Is Vaginal Cesarean Section Justifiable? — Dr. PALMER FINLEY of Chicago read a paper with this title, in which he drew the following conclusions: (1)

Less time was consumed in delivering the fetus by the abdominal route. (2) Greater accuracy was assured in surgical cleanliness by the abdominal route. (3) The abdominal incision was wholly under control of the operator, whereas in the extraction of the fetus per vaginam the incision might extend beyond the control of the operator, as it had in more than one case, and with fatal results from hemorrhage and infection. (4) In an abdominal cesarean section opportunity was afforded of rendering the patient sterile by resecting the tubes when thought advisable, and various lesions, such as adhesions, tumors of the uterus demanding hysterectomy, bands as the result of ventrofixation, and diseased appendages could be dealt with. (5) The abdominal route assured the fetus of the greatest consideration, inasmuch as the application of forceps and the turning of the child in utero were necessarily attended by dangers to the fetus. (6) Rupture of the uterus in subsequent pregnancies through the scar of a cesarean section was a not uncommon accident, and it was apparent that since the large majority of ruptures of the uterus were in the lower uterine segment, a scar at this point would more likely be disposed to rupture than one located in the fundus. There were as yet no records of injury to the bladder and ureter, and the limited time since the introduction of the operation left us in doubt as to the dangers from rupture of the lower uterine segment in future pregnancies, but might we not with fairness anticipate such accidents and therefore proceed with caution? Returning to the original question propounded in the subject of this discussion, the author would answer, in the light of the reported cases, and judging by the results obtained in the use of other well-established methods of delivery in cases similarly indicated, that vaginal cesarean section was not destined to find general favor with trained obstetricians, and that the legitimate scope of the operation would be so limited that it would be little practised. And yet we might expect that it would remain in general favor with a few obstetricians.

The Surgical Treatment of Total Prolapse of the Uterus.—Dr. C. O. Thienhaus of Milwaukee said the fact that many surgical methods were devised for the treatment of total prolapse of the uterus demonstrated that possibly none of them was absolutely perfect and adjustable to every case. The author believed that those methods which made the use of the body of the uterus as a support to the bladder were to be preferred, because thereby a recurrence of the accompanying cystocele, which so often took place after other methods of surgical procedure, was made absolutely impossible. He described at length a method used by himself, a modification of that employed by Schauta and Dührssen, and reported nine cases upon which he had operated, with satisfactory results.

Dr. A. H. Cordier of Kansas City saw no objection to departing from some of the older methods for holding the uterus in its proper position. It was his custom to do a ventrofixation operation in old patients, doing complete repair of the perineum, both anterior and posterior, and not simply making a flap in the vagina, but repairing the muscles, reestablishing them, and putting the uterus in normal position.

Dr. O. Beverly Campbell of St. Joseph, Mo., said there was a class of cases in which the procidentia had remained for a long time, in which the vaginal mucosa had ulcerated to such an extent that it was almost destroyed, and he had seen a few such cases in which he believed the more radical operation of Professor A. Martin, or removing the entire vagina and uterus, and closing up the opening, would give better results than the operation described by Dr. Thienhaus. This was especially true in old women, say sixty-five years of age, old maids or widows, for whom matrimony did not enter as a factor. Ventrosuspension for the cure of procidentia had been a most unsatisfactory procedure.

Tumors of the Cerebellum.—Dr. F. E. Coulter of Omaha read a paper on this subject, in which he reported a case. The author dealt with the question of neoplastic growths in the posterior fossa of the skull, taking up the etiology, symptomatology, and diagnosis. He emphasized the more common signs and symptoms of disease in this location, thus making of more practical importance the questions of diagnosis and treatment.

Blastomycetic Dermatitis.—Dr. William Frick of Kansas City, Mo., said that while this could not be considered a very common disease, it was more frequent than was generally supposed, especially in the inland portions of America. He referred to the number of cases found in the literature, and briefly reported three that he had observed. The histopathology of the three cases was practically the same as that described by other observers. There were a few things about it which made a striking and typical picture. There was increased proliferation of epithelium, the interpapillary plugs extending deep into the corium, and sometimes being distorted. There was also the presence of whirls, as seen in epithelioma, but the epithelium held together and was not bound down in the connective tissue structures cut off from the epithelial layer, as in cancer. The most characteristic thing appeared to him to be the miliary abscesses which were found both in the epidermis and in the corium. It was in these abscesses that the organism was most abundantly found. Another interesting point was the large number of giant cells resembling those seen in tuberculosis. For the present, the treatment consisted in excision, the administration of iodine compounds, and the use of the *x*-ray. Since the point of entrance was usually some exposed surface of skin, if an early diagnosis was made, a complete excision would usually end the case, and was the quickest and most satisfactory method of disposing of it.

Dr. Charles G. Geiger of St. Joseph, Mo., detailed a typical case of this disease which he saw about a year ago. He discussed the differential diagnosis of blastomycosis from tuberculosis verrucosa cutis, fungous syphiloderm, and lupus vulgaris.

Intestinal Tuberculosis and Its Surgery.—Dr. L. L. McArthur of Chicago delivered the Address on Surgery. He stated that with the reopening of the question which had hitherto been accepted as settled, that infection in tuberculosis almost invariably occurred through the respiratory tracts, the latest and more painstaking observations show that through the intestinal tract a far larger number of cases of infection existed than had been thought or deemed possible. Practically, nursing children and milk-fed infants were the only ones who were afflicted with true primary intestinal tuberculosis, because (1) they were the ones exposed most commonly to infected foods; (2) their intestinal tracts were less resistant to such invasion. Eisenhardt, in one thousand autopsies of tuberculous adults, found 563 cases of intestinal infection, of which 489 had cavities in the lungs, and 74 had not. Intestinal tuberculosis was frequently overshadowed by the pulmonary disease; but inasmuch as the presence of cavities determined so regularly the intestinal infection, the absence of cavity would have a decided prognostic value in those cases that clinically came to the surgeon for aid. These would, in the largest proportion of cases, be over twenty-five years. After discussing at length the varieties of intestinal tuberculosis, and the treat-

ment from both a medical and surgical standpaint, the author's study of the literature, and his personal experience, led him to the following conclusions: (1) The term primary tuberculosis of the intestines was both clinically justified and often demonstrable on section. (2) That in selected cases, though desperate, surgical interference offered reasonable hope. (3) That the capacity for withstanding surgical interference was greater for this condition than that which obtained with other abdominal affections of like magnitude. (4) That the first symptoms of this disease might begin as, and even be mistaken for, an appendicitis. (5) That partial or total exclusion would in some cases accomplish the desired results when conditions contraindicated excision. (6) That the ulcerative variety might make numerous fistulæ, as in the author's cases. (7) That simple inflammatory processes were apt, in a tuberculous subject, to become tuberculous. (8) That surgery offered much hope to an otherwise probably fatal issue. (9) Many a case of general abdominal tuberculosis was the end result of a preceding intestinal tuberculosis which might have been at one time operable. (10) Both bovine and human tubercle bacilli, while not identical, were related varieties of one original form. (11) That the cutaneous hand infections of butchers were a strong argument against absolute difference.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held January 16, 1906.

DR. CHARLES H. LEWIS IN THE CHAIR.

A Case of Myxedema.—Dr. J. FINLEY BELL of Englewood, N. J., presented this patient, whom he had had under observation for several years. Photographs were shown, by which it was seen that the improvement under five weeks of treatment with thyroidin was very marked.

A Case of Typhoid Fever Complicated in Its Prodromal Stage by Jaundice.—Dr. WARREN COLEMAN said that jaundice was one of the rarest complications of typhoid fever and that Sir William Jenner never had seen a case, while Murchison saw only four cases, and Griesinger observed it ten times only in 600 cases of typhoid fever. Liebermeister reported that it occurred twenty-six times in 1,420 cases, while others had reported it to have occurred in the percentage of 1 to 1½. Jamieson, on the other hand, writing from China, said that jaundice was generally present to a greater or less extent in prolonged cases of typhoid. It seemed, therefore, that jaundice complicating typhoid fever was common in China. Jaundice usually occurred late in typhoid fever, but might occur in the first week. In the case Dr. Coleman wished to report jaundice developed five days before the onset of the fever; in fact, during the first two days in the hospital the temperature was subnormal. The patient was a man, 38 years old, who entered Bellevue Hospital July 23, 1904, giving a history of excessive indulgence in alcoholic stimulants. His physical examination on admission showed an alcoholic appearance with a deep yellow hue over the entire body, the conjunctiva having a deep orange color. The case presented the course of a mild typhoid, and the following points in the subsequent history were worthy of notice: The pulse was persistently rapid and dicrotic. The stools were clay colored, a very unusual thing in the jaundice of typhoid. There was nose bleed on the fourth day of the fever and the ninth day of the jaundice. There developed a few petechiæ on the legs, one the size of a dime. At no time were they able to find rose spots. The blood examination gave no organisms of any kind. The serum reaction, though negative at first, became positive to typhoid at 1:2000. The serum reactions with the clinical course of the disease were sufficient to establish a diagnosis of typhoid fever. Dr. Coleman said that Osler had grouped the cases of jaundice occurring in typhoid fever into four classes: the catarrhal, the toxic, those associated with gallstones and cholecystitis, and those associated with abscess. DaCosta stated that the catarrhal cases were rare, and six of the eight cases seen by Osler belonged to this group. Apparently the earlier the jaundice the more likely was it to be due to a catarrhal cholangitis, and, consequently, more serious. His case was probably of this nature. Recently evidences had been adduced to show that catarrhal cholangitis might be caused by the typhoid bacillus in the absence of typhoid fever (Müller). Dr. Loomis had reported such a case seen at Bellevue Hospital this autumn. It had been proven that the bacillus typhosis might cause cholangitis without and relation to typhoid fever. In DaCosta's case and in the one he reported it was probable that the typhoid bacillus attacked the biliary passages and the body at large at the same time. The cases of toxic jaundice belonged to the category of hepatic toxemias and extreme cases resembled acute yellow atrophy. They occurred late in the disease, and often ended fatally. In abscess of the liver jaundice was not always a concomitant when abscess of the liver complicated typhoid fever. Cholangitis as a complication of typhoid fever had been so extensively studied that a consideration of it was unnecessary in this connection.

Dr. SHERMAN asked if there were any evidences of an alcoholic gastritis.

Dr. COLEMAN answered no. The man, however, was a decided alcoholic and the jaundice was very deep.

A Case of Henoch's Purpura with Severe Visceral Crisis.—Dr. T. STEWART HART reported this case. The patient was a boy, aged 15 years, who was admitted to the Seton Hospital on August 12, 1904. The family history was negative. In 1904 he was admitted to Bellevue Hospital, where a diagnosis of pulmonary tuberculosis was made. When admitted to Seton Hospital he had well-marked pulmonary lesions with signs of cavity in the left upper lobe, was considerably emaciated, and seemed quite ill. For a time he was kept in bed, but gradually he began to improve and was allowed to be up and out of doors. After having been in hospital for about six months he came in from coasting, claiming that he had injured his right foot. On examination a number of bright red spots between the toes of both feet were found. They were discrete and did not disappear on pressure. The right ankle was swollen and somewhat tender. The spots gradually increased, extending up the anterior aspect of the legs, and, in two days, they reached the knees, at first appearing as distinct spots, soon becoming confluent, and as the areas became older they changed to the characteristic dark bluish areas. On February 25 large ecchymotic areas were noted over the anterior parts of both thighs. On February 28 there were pain and stiffness in all the joints of arms and legs, with large purpuric areas over arms and forearms, with some scattered areas over chest and back. On March 16 abdominal pain was complained of, and he vomited several times during the day. The left iliac region was tender and rigid. Temperature was 99°, pulse, 86. During March 17 he vomited all night and all day, mucous and bile. On the 18th and 19th he felt much better. On March 22 he was seen by Dr. Lee, who agreed that the diagnosis was probably peritonitis, but he advised against operation. There was a polymorphonuclear leucocytosis of 26,300. On March 23 there was vomiting, the abdomen was tender and rigid, and rectal feeding was begun. The temperature ranged higher every day from March 21 to 28, when it reached 103.2° and then gradually subsided. From this time there was a gradual improvement and on March 30 the patient was allowed to sit up. For two weeks longer he continued to have purpuric spots over the extremities, with pains in the ankles. The point of interest in this case was the extensive purpura complicating tuberculosis. This case might be classified as a Henoch's

purpura with the characteristic visceral crisis. In this case the expression of the face, the vomiting and diarrhea, the extreme general tenderness and rigidity of the abdomen, with a considerable leucocytosis, all indicated a picture of peritonitis. There were many theories of purpura advanced, and the most fascinating was that of Flexner, who suggested the possibility of a lesion in the blood which dissolved the endothelial cells, permitting hemorrhage into the subcutaneous tissue.

Dr. L. F. Bishop said that at the Lincoln Hospital there was admitted a man with a marked purpura, particularly over the chest, who vomited everything placed in the stomach and who had to be placed upon rectal feeding. After two days the vomiting ceased. This man he believed to have had a gastric crisis in the purpura.

Dr. Heinrich Stern discussed this report.

A Report on the Clinical Chemistry of the Blood in Various Diseases.—Dr. H. S. Carter presented this communication, showing the findings particularly in three diseases: chronic diffuse nephritis, illuminating gas poisoning, and pneumonia. A few cases of scattered diseases were also reported. Altogether he reported the findings in 117 cases, giving the estimation of the percentage of total chlorides and the urea in the blood. The normal percentage of urea in the blood ranged from 0.01 to 0.04, and the chlorides 0.6. The percentage of chlorides (0.9) was isotonic with that of the blood.

Chronic Interstitial Nephritis.—Thirty-nine cases were reported, and this series was divided into the fatal and the non-fatal cases, and also whether they were suffering from convulsions or not. The division was purely an arbitrary one. The total amount of urine passed in twenty-four hours in the fatal cases was 950 c.c.; in the non-fatal cases, 1,280 c.c.; the specific gravity among the fatal cases was 1,015; in the non-fatal cases, 1,015; the amount of albumin in the fatal cases was 7.9 per cent., and in the non-fatal, 4.3 per cent.; the percentage of urea in the fatal cases was 1.63; in the non-fatal cases, 1.36; the amount of urea in twenty-four hours in the fatal cases was 14.02 grams; in the non-fatal cases, 15.4 grams; the percentage of chlorides in the fatal cases was 0.21, and in the non-fatal cases, 0.66; the chlorides in twenty-four hours in the fatal cases amounted to 2.1 grams, while in the non-fatal cases it was 10.2 grams. The examination of the blood in all cases gave an average of urea 0.207, and the average of chlorides, 0.67 per cent. In the cases with convulsions the average of urea was 0.25 per cent., the average of chlorides was 0.6 per cent; in the cases without convulsions the average of urea was 0.2 per cent., the average of chlorides was 0.63 per cent. (these at a temperature of 63 C). For all of the non-fatal cases the average of urea was 0.76 per cent., and of the chlorides, 0.65 per cent.; of the cases with convulsions the average of urea was 0.078 per cent., the average of chlorides, 0.6 per cent.; of the non-fatal cases without convulsions the average of urea was 0.077 per cent., and the average of chlorides was 0.76 per cent. The following were the points of interest among these 39 cases of chronic interstitial nephritis: (1) The total amount of urine, specific gravity, percentage of urea in the fatal and the non-fatal cases varied within narrow limits; (2) the percentage of chlorides and the total amount of chlorides in the urine of the immediately fatal cases were lower than those with temporary improvement; (3) in the blood the average percentage of urea in the fatal cases was three times as great as in the non-fatal cases; (4) the average percentage of chlorides was not of great difference; (5) the presence or the absence of convulsions in the fatal and the non-fatal cases did not seem to be associated with the amount of urea or chlorides.

Illuminating-Gas Poisoning.—There were 20 of these cases examined. In 7 of them the symptoms were mild in character and they were transferred to other hospitals, therefore data were not obtained. There was an increase in the total chlorides in the blood in most of these cases. In 11 cases in coma there was a notable increase. When the patients were under 30 years of age the chlorides were high in percentage. Only 1 case showed any marked leucocytosis. A secondary count showed a decreasing leucocytosis and of the polymorphonuclear variety. So far as the percentage of urea was concerned there was a very narrow limit in the fatal and non-fatal cases, averaging about .05 per cent. There were but 3 fatal cases, only one though being due to the gas poisoning itself; one was due to a bronchopneumonia, and another to abscess of the lung. In an examination of the blood in these cases the following points were of interest. Where exposed eight hours or more there showed a total chloride of 0.91 per cent.; cases in coma showed 1.02 per cent.; cases with temperatures 102° or over showed 1.31 per cent.; cases under 30 years of age showed 1.26 per cent.; cases over 40 years of age showed 0.64 per cent.; leucocytosis, 18,000. There was no notable increase in the urea. This showed quite a variable amount of chlorides in the blood.

Pneumonia.—There were 16 cases, with four recoveries and twelve deaths, rather a high percentage of fatal cases. An examination of the blood in the non-fatal cases showed 0.78 per cent. chlorides, 0.053 per cent. urea, and 20,000 leucocytes. In the fatal cases there was 0.96 per cent. chlorides, 0.8 per cent. urea, and 10,000 leucocytes. Where one lobe was involved the urea amounted to 0.066 per cent., where two lobes were involved, 0.083 per cent., and where three or more lobes were involved, 0.11 per cent. This showed a decided increase of urea in the fatal cases. When there was cyanosis the urea percentage was higher, irrespective of the lung involvement. Irrespective of the termination or complications, the greater amount of tissue involved gave a higher percentage of urea in the blood. Dr. Carter then referred to some miscellaneous cases that had been examined, such as chronic endocarditis, alcoholic dementia, chyluria, gastric carcinoma, hysteria, tuberculous pleuritis, cerebral hemorrhage, diabetes, epidemic cerebrospinal meningitis, etc., but data were deficient on which to base any important findings.

Dr. George A. Tuttle said that the work done by Dr. Carter was at his suggestion, but the results had not quite met their expectations. He said that Widal had observed in cases of nephritis with general anasarca that if he limited the amount of chlorides ingested the anasarca disappeared; but if salt was again given, the anasarca reappeared. In one case this was repeated nine times with the same result each time. The observations of Dr. Carter had not yet been carried far enough to be of great value. The cryoscopic results did not agree with the chloride results.

Dr. C. A. Herter said that some years ago he made use of the urea determinations in the blood, especially in relation to cases of chronic nephritis; he also made some observations upon cases of pneumonia. The results he obtained were not unlike those obtained by Dr. Carter, and which he had recorded in a paper in Welsh's "Festschrift." There was one point that came out in his studies, and that was that a study of the urine as regarded the urea was of little aid in reaching any conclusions as to whether the urea in the blood was increased or not. It was possible to have for a long period of time a small reduction of urea in the blood of various organs without showing any demonstrable falling off in the amount of urea in the urine. It was interesting to note that the fatal cases in his series of cases showed such a higher percentage of urea than the non-fatal. He said that if an animal, like a monkey, was infused with urea, when the blood content was reduced to .5 per cent., twitchings or general convulsions appeared, and he had often wondered if it was not likely that when they got a percentage of urea which approached the limit mentioned, whether the urea could not be regarded as contributable in the production of the violent nervous disturbances. Again, when the urea in the blood amounted to .4 per cent., one found that there was apt to be some elimination of urea by the intestinal tract. In three dogs in which infusion of this sort had been made there was

an increased peristalsis followed by an actual catharsis. If one went higher than .5 per cent. of urea in the blood then there would appear congestion, or hemorrhages in various parts of the intestinal tract, especially in its lower portion. This seemed to him to be a clear case of elimination. In those cases of chronic nephritis in which there was a persistent diarrhea and high urea content in the blood, with evidences of congestion and hemorrhage, sometimes even ulcerations, in those cases he thought they were dealing with one of the manifestations of accumulation of great excesses of urea.

Some Relations of Chronic Intestinal Putrefaction to the Severe Anemias.— Dr. C. A. HERTER presented this communication. After referring to some properties of indol, skatol, methyl indol, with demenstration of color reactions (see MEDICAL RECORD, December 16, 1905, p. 997), he briefly summarized by stating that there were a number of cases of anemia occurring in infancy associated with very marked increase in intestinal putrefaction, and that it was reasonable to suppose that the anemia bore some relation to the putrefactive changes, for the reason that when the putrefactive changes let up the patients improved. Ideal conditions for this study were offered by children, because, in the first place, they were not subject to innumerable diseases and because they could be brought under good control and the mental factor could be eliminated. The probabilities were that there were rather severe secondary anemias in children connected with excessive intestinal putrefaction. There were cases in older children, and in adults, where a moderate degree of secondary anemia appeared to be intimately associated with putrefactive disturbances. That the severe anemias could really be said to be due to the existence of putrefactive changes did not appear to be clear. The interpretation of the phenomenon was difficult. By the use of certain methods he said it might be possible to get a clearer view of the processes that contributed in bringing about the severe forms of anemia.

Dr. E. K. DUNHAM asked if Dr. Herter could not give some scheme by which the examination of the urine would throw some light upon the intestinal putrefaction.

Dr. T. STEWART HART asked if the anemias with an absence of hydrochloric acid from the stomach would not be helped by the administration of this acid.

Dr. LEWIS A. CONNER asked if the constant relation between the diminution of the quantity of the gas forming in the sugar media and evidences of intestinal putrefaction in urine were present.

Dr. HOUGHTON asked if in cases of pernicious anemia cures had been produced by washing out the bowels with so-called antiseptics.

Dr. C. A. Herter said that the up-waves and down-waves of pernicious anemia might be benefited by rest and diet and in a few months patients might leave the hospital and remain well for some time without any special attention being paid to intestinal conditions beyond those mentioned. In answer to Dr. Connor's questions he did not think that any such relation existed, but he did believe there was some relation between the diminution of the amount of gas production and the production of mercaptans. All cases showing mercaptans indicated to him that the individual was very ill. In answer to Dr. Hart's question he said that the presence of hydrochloric acid influenced the putrefactive changes a great deal; the anaërobes did not get along well in neutral or acid media, but thrived well under a moderately alkaline media. Some diarrheas were, no doubt, due to putrefactive products. If indican was present in excessive amounts diarrhea followed; when large quantities were present it was impossible to have large and well-formed stools. The removal of the putrefactive produces led to a diminution in the absorption and a falling in the amount of ethereal sulphates and other evidences of putrefaction in the urine.

Election of Officers.— *Chairman*, Dr. Warren Coleman; *Secretary*, Dr. E. E. Smith.

JOINT MEETING OF THE CHICAGO SURGICAL AND MEDICAL SOCIETIES.

AT the meeting held February 28 Dr. J. M. T. FINNEY of Baltimore, Md., read a paper entitled "Post-Operative Intestinal Obstruction." After referring at length to the literature of the subject, and detailing twenty-six cases, that had occurred in the practice of the author, the following conclusions were drawn: (1) Broca's classification into early and late varieties simplified the diagnosis. In the former class, which so frequently was associated with peritonitis, the differential diagnosis as to variety was always difficult and often impossible. In the latter, which was composed almost exclusively of the mechanical forms, it was unusually easy. (2) Adhesions were the chief factor to be reckoned with in an attempt to prevent the occurrence of post-operative ileus, and efforts directed toward this end were likely to be productive of the best results. (3) That drainage exercised a marked influence in the production of adhesions could not be denied. (4) Prompt operation was indicated in every case after palliative measures had been given a fair trial and had failed. The character of the operation depended upon the nature of the obstruction and the condition of the patient. (5) The prognosis was unfavorably influenced by the presence of infection. In its absence it was excellent. Dr. JOHN B. MURPHY defined ileus as a train of symptoms consisting of pain in the abdomen; nausea and vomiting; meteorismus, and coprostasis. Using this as a guide, he subdivided ileus into adynamic ileus, dynamic ileus, and mechanical ileus. He discussed at length the different forms of ileus. One of the first causes of adynamic ileus was strangulation of the omentum. The colic which occurred with hepatic calculus was difficult to differentiate from mechanical obstruction, because there was pain, nausea, and vomiting, absence of peristalsis, with distention of the bowel coming on as the result of the paralytic condition; also coprostasis while the pain was severe. One of the very difficult conditions to diagnose differentially was the impaction of stone in the cystic duct. Gastric tetany was another condition mistaken for intestinal obstruction. Peritoneal trauma was the cause of paralytic ileus. The embolic type of paralytic ileus was due to two causes —interference with the nerve supply, and ischemia. Temperature was never a primary symptom in mechanical ileus. He had ceased to place any particular value on the differential diagnosis from the number of leucocytes. Dr. ARTHUR DEAN BEVAN said that strangulation ileus was best studied from the standpoint of a strangulated hernia. It was a form of ileus which came on as a strangulated hernia did, with sudden onset, shock, pain, obstruction of the bowel, vomiting, with, later, tympany, and, if unrelieved, peritonitis usually occurred, followed by death. At the beginning it was free from temperature. The diagnosis could be made early if the surgeon had a clear mental picture of what strangulation ileus meant. He discussed the character of the operation in these cases, and mentioned the conditions found as the cause of mechanical ileus when the abdomen was opened. Meckel's diverticulum was the cause of probably more than five per cent. of the cases of intestinal obstruction. A long appendix, or adhesions to a tube, might cause obstruction. A most common cause was volvulus. He recently saw a case of volvulus of the entire transverse colon which caused obstruction. The proper treatment of a case of strangulated ileus was immediate operation. Patients with mechanical ileus died because an early diagnosis was not made, because early operation was not done, but in whom early diagnosis and early operation would have saved life. Dr. WILLIAM E.

Schroeder mentioned the classification of Schlange, who considers obturation ileus as including compression from without, strictures, both begin and malignant tumors in the lumen of the intestine, intussusception, and the usual obturation forms, namely, from gallstones, enteroliths, foreign bodies, and fecal masses. The nature of the obstruction consisted in the simple closure of the lumen of the intestine, either primarily from within or through compression from without. After discussing the symptoms of the acute forms of obturation ileus, also the diagnosis, he said that enterostomy was of especial value in relieving the intestine of its poisonous contents and because of the simplicity of the operation. A radical operation might follow at some future time when the patient was in better condition. In strangulation ileus it was necessary to relieve the strangulated intestine and save it from gangrene, or to resect the gangrenous portion. Cases of ileus came into the hands of surgeons too late. Many general practitioners waited for fecal vomiting before they transferred their cases to the surgeons. Dr. M. L. Harris discussed the abuse of cathartics in obstruction of the bowels. He mentioned cases illustrating all the varieties of intestinal obstruction, and summarized by saying that cathartics should never be given to a patient suffering of an acute abdominal trouble until a diagnosis had been made, or if not an accurate diagnosis, at least until all of the conditions which might produce obstruction had been positively excluded, and it should be remembered that these patients were never sick because the bowels did not move, but the bowels did not move because they were sick. Dr. Fernand Henrotin said there were many cases in which catharsis was given when the diagnosis was not clear, where the symptoms were not typical, so as to render the making of an accurate diagnosis more easy, and in such the administration of a cathartic was permissible. He spoke of the value of enterostomy in cases of ileus, and of not stopping to do a radical operation in the advanced cases. Dr. Finney, in closing, said that surgeons were agreed that cathartics had a limited place, but their administration should not be overdone.

San Francisco County Medical Society.

At the regular monthly meeting of this society, held February 13, 1906, Dr. Simon Baruch of New York City read by invitation a paper on "The Rôle of Hydrotherapy in Chronic Diseases." He said that at no period in its history had the medical profession been menaced by empirics as it was at the present time. He referred to the "nature" physicians (Naturärzte) who had made such encroachments upon the regular profession that the universities had been constrained to add the teaching of physical therapeutics, especially of hydrotherapy, to the medical curriculum. It was only in this way, the speaker said, that the young physician could be fortified to meet the attacks of the quacks who besieged their drug-weary patient with the bright promise of nature's beneficial methods. The board briefly reviewed the physiological estimate of the action of cold and heat upon the vast network of blood-vessels and nerves of the skin, and insisted that inasmuch as the latter were the vast outlying portions of the central nervous and circulatory systems powerful effects upon arterial supply, blood pressure, and metabolism must ensue when cold and hot water was applied judiciously in accordance with the capacity of the patient to respond. The speaker expressed his gratification from observing the great interest his address of two years ago had aroused on the Coast, as was testified (1) by his discovery of the most complete hydriatic equipment at Paso Robles; (2) a request for advice from Dr. Stocking of the Agnew State Hospital, how to spend an appropriation of $10,000 for a hydrotherapeutic equipment; (3) an invitation to meet the architect, visiting staff, and building committee of the German Hospital for council on the best mode of constructing a hydriatic department in the new hospital, and (4) the invitation to address this great society on hydrotherapy. Such incidents had made his work a labor of love. From an abundant material, containing failures as well as successes, Dr. Baruch offered illustrations of clinical results; one from his hydriatic clinic, of sciatica of two years' standing, which had resisted all treatment, including a stay at Mt. Clemens, and the routine douche treatment, for which the patient had been referred to by the Vanderbilt Clinic during his absence. This case was entirely cured by a method of bathing in water at 108° and subsequent packs, continued for two weeks. He also referred to a case in his hospital service of supposed gastric ulcer, for which a gastrojejunostomy had been unsuccessfully done and which he diagnosticated as a gastric neurosis and which was entirely restored by a graduated system of cold procedures. He cited the statements of Erb, Senator, Krafft-Ebing, Collins, and Draper in favor of hydrotherapy, and the fact that in his hydriatic clinic the number of treatments had increased from 2,000 in 1906 to 10,000 in 1904, the cases having been referred by most of the hospital outdoor departments and college clinics in New York. In conclusion, he made an earnest appeal for the instruction in hydrotherapy, and stated that he had been requested to deliver a course of lectures in hydrotherapy in the College of Physicians and Surgeons, a happy augury that the present unfamiliarity of medical men with the rationale and technique of hydrotherapy might cease to be a reproach in the future. The paper was discussed by Drs. Sanderson and Parsigan, who cited cases favorably influenced by hydrotherapy, and Drs. Rosenstirn and Evans, who approved of the idea that hydrotherapy be taught in the undergraduate schools and to hospital staffs and nurses. Dr. Power thought that the curriculum was already overcrowded. Dr. Baruch closed the discussion. He replied that if the present teaching of the inert and obsolete remedies were abandoned, the course of materia medica might well be abbreviated, and the now wasted time devoted to teaching massage, hydrotherapy, etc. He said that ten years ago the late Gaillard Thomas proposed to the then dean of the faculty of the College of Physicians and Surgeons of New York to add hydrotherapy. It was not done because the curriculum was overcrowded. The present dean, however, recognized the importance of teaching the students something besides the use of drugs.

The Treatment of Cerebrospinal Meningitis.—F. E. H. Maerker, having repeatedly observed the beneficial effects of the hot bath in the treatment of myelitis, locomotor ataxia, and other spinal affections, it occurred to him to make use of it in meningitis. The first effect of the immersion of the body in the hot water bath was a shock to the nervous system, caused by the impact of the water upon the body. The surface is first blanched, but soon becomes pink, due to the reaction. The effect of the bath upon the heart is that of a powerful tonic. The cardiac action becomes stronger, and the force of the contractions increased. The lost tone of the vasomotors is restored. The current of fluid is increased, for the heart, in order to act well, must meet with proper resistance. The cellular elements of the blood are increased, as well as the hemoglobin. The demonstration of an increase in leucocytes is an important factor. Depth of respiration, which is increased, is favorable to the restoration of the relative percentage of absorbed O and exhaled CO_2. Elimination of toxins takes place, as is shown in the amelioration or complete subsidence of symptoms. The writer describes several cases in which the results of this treatment have been most happy.—*The Ohio State Medical Journal.*

* No reciprocity recognized by these States

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Michigan reciprocates with Wisconsin, Indiana, Iowa, Kansas, Nebraska, Maryland, Minnesota, Wyoming, Missouri, Nevada, South Carolina, Maine, Vermont, Georgia, Illinois, Ohio, New Jersey and North Dakota.

Vermont reciprocates with Maine, Maryland, and New Jersey.

Maine reciprocates with Vermont, New Jersey, Maryland, South Carolina, Georgia, Texas, Ohio, Iowa, Indiana, Illinois, Missouri, Wyoming, South Dakota, Minnesota, Wisconsin, Michigan, and District of Columbia.

Kansas—Reciprocal relations have been established by Kansas with the following States: Missouri, Illinois, Indiana, Maryland, Michigan, Wisconsin, Iowa, Nebraska, Minnesota, New Jersey, Wyoming, and South Carolina.

New York.—In the annual report of the State Board of Medical Examiners it is stated that the total number of (regular) candidates examined from July 31, 1904, to August 1, 1905, appearing for the full license was 421; of these 331 passed and 90 were rejected. In the primary medical examinations there were 354 candidates, of whom 338 passed and 16 failed. In the final subject only there were 318 candidates, and 313 passed, and 5 were rejected. The total number of candidates for license was 810, against 778 last year, 756 in 1903, and 685 in 1902. The total number of examined candidates who appeared before all three boards was 1,195. Sixteen of these received certificates "with honor." The rejections per topic for the year were as follows: Anatomy, 47; physiology and hygiene, 50; chemistry, 42; surgery, 28; obstetrics, 48; pathology and diagnosis, 28; therapeutics, practice, and materia medica, 33. Average rejections per topic, 30.4.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 7, 1906.

THE CONDITION OF THE AIR OF THE NEW YORK RAPID TRANSIT SUBWAY.*

By GEORGE A. SOPER, Ph.D.,

NEW YORK.

CONSULTING SANITARY ENGINEER.

It is my intention to-night, with the courteous permission of the Board of Rapid Transit Commissioners, to bring to your attention some of the most interesting and significant results of a six months' investigation of the condition of the air of the New York subway.

The Board of Rapid Transit Commissioners is, as you know, the body which has had official charge of laying out the road, building it and supervising its operation. Under their supervision several hundred million dollars worth of additional subways are yet to be built.

The main object of the investigation was to determine whether any harmful matters or conditions existed in the subway to such an extent as to make the air in any degree a menace to the public health. There were other objects and other problems studied, but the only matters to which I will refer here relate to the condition of the air from a strictly sanitary standpoint.

The methods employed depended largely on the use of chemical and bacteriological analyses. I was not authorized to examine into the health of the employees, although to have done so might have proved an important feature of the work.

The investigation began in July and ended in December. There was thus afforded an opportunity for observing the conditions during different seasons of the year. The average number of my assistants was ten. I take pleasure in saying that it is largely to their ability that the following results have been obtained.

For about a year, now, the overheating of the subway has been a matter of so much public interest that our attention may well be directed to the question of temperature first. The overheating first became noticeable in the middle of March, 1905. At this time, according to the records of the preceding year, the temperature inside and outside of the subway should have been about the same, but it was warmer. As summer came on, the subway air remained warmer than the outside air when it should have been cooler.

Before the subway was opened, its temperature during its hottest week was 18.3° F. cooler than the air in the streets. After it was opened, its average temperature during its hottest week was 5.2° warmer than the outside air. The average of the daily temperatures noted in the subway during this week was 83.4°. The maximum temperature observed in the subway during this hottest week was 88.2°. In the street it was the same at the same time.

The coldest temperature observed by me in the subway during the present winter was 30°. This occurred at the Canal Street station. It was 16° warmer here than in the streets.

So far the difference between the temperature of the subway and streets has been much less in summer than in winter. In July and August, 1905, the average temperature of the subway was 5.6° higher than that of the streets, but in the first part of November the difference was over 15°.

In the middle of November, the routine work of collecting and interpreting the records of temperature was turned over by me to the engineers of the road and I have no knowledge of the general averages since.

In view of the fact that European subways appear to become warmer year by year, the increasing excess of temperature of our subway over the outside air, as noted by me up to last November, leads me to look forward to the possibilities of the coming summer with peculiar interest.

The cause and remedy for the overheating of the subway are being made the subject of study by

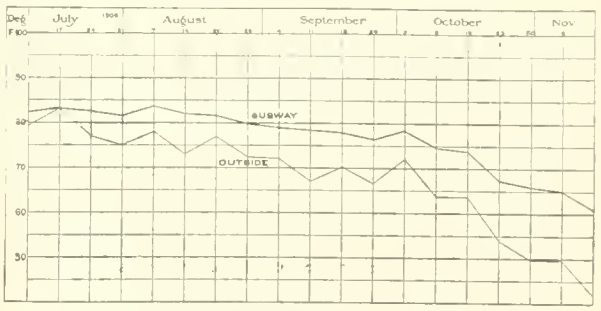

FIG 1.—Relative average temperatures of the air in the streets and subway.

the Chief Engineer of the Board of Rapid Transit Commissioners, Mr. George S. Rice. If his work is successful, and we all trust that it may be so, we may have a cooler, rather than a warmer, road next summer. In consequence of the comprehensive work which I am informed Mr. Rice is carrying on in this direction, it seems inappropriate for me to discuss this phase of the subject further to-night.

Sanitary considerations do not lead me to regard the heat of the subway, as shown by last summer's figures, with alarm. It is difficult to see how the higher temperatures which have occurred at this season could alone produce injurious effects upon health. But if the heat is not unhealthy, it is at least disagreeable, and if it proves to be a practical undertaking, the subway

*Paper presented before the New York Academy of Medicine on March 15, 1906.

should by all means be kept cool. In hot weather the subway is most uncomfortable in the morning and at night. At these times, the air does not cool off as does the air in the streets. In the most tightly closed portions of the subway the temperature remains nearly constant through the twenty-four hours. Some stations are always warmer and more even in temperature than others. Express stations generally become overheated and cool more rapidly than local stations. As a rule, those places which are most open to the outside air respond most rapidly to changes of temperature in the streets and have, on the whole, the lowest average temperatures.

The conditions in winter, when strong draughts of cold air enter the stations, seem far more apt to prove injurious to health than the conditions in summer. In the winter the temperature of the air near the entrance at some of the stations changes so rapidly that the most sensitive recording thermometers are far too slow to record them.

By means of a very delicate, ventilated thermometer, made especially for the purpose, some idea of the rapid rises and falls was obtained. In one case, when the subway air was 59.5 a drop of 12.5° was noted in less than one minute and a half. In another case, a change of 7° occurred in one minute. Still greater and more rapid variations than these undoubtedly took place, but the mercury in even this very sensitive thermometer was too slow to show them.

Leaving now the question of temperature, we may direct our attention for a moment to the subject of humidity. During the period covered by my investigation, the subway air has been practically as dry as the air of sheltered places in the streets. The dew point, that is, the temperature at which moisture begins to condense from the atmosphere has been, on the whole, little higher inside than outside, but the relative humidity, or degree of saturation, has been lower in the subway than in the streets. In other words, there has really been a little greater weight of water in the air of the subway than in that of the streets, but, because of the higher temperature, the subway air has not been so nearly saturated.

The average relative humidity of the subway for July and August, 1905, was 57.5 per cent. and

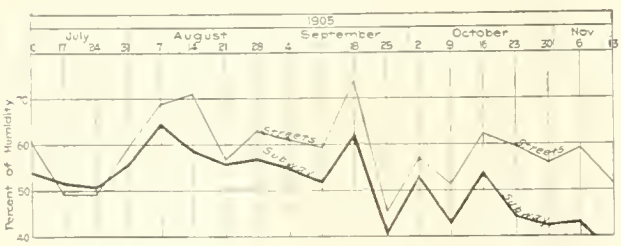

FIG. 2.—Relative humidity of the air of the streets and subway.

of the outside air 60.6 per cent. The greatest average humidity for any week in the subway happened to occur during the week which was also the hottest. The average humidity for this period was 64.4 per cent. As a rule, changes in the dew point and relative humidity in the subway followed similar changes out of doors. At no time has there been a pronounced fog or mist. A fine haze has not been uncommon. This has been most noticeable where shafts of sunlight have penetrated the atmosphere. This haze has been due to dust, not to moisture.

Chemical analyses were made of the air to determine, first, whether there was a sufficiency of oxygen present and second, to what extent the air was vitiated by the products of respiration. All the air examined chemically was collected in special receptacles made for the purpose. It was usually analyzed on the day on which it was collected, or the day after. Samples were taken at stations, and between stations, and at different times. For purposes of comparison, samples of air were usually collected in the streets whenever samples were taken in the subway.

It is interesting to note that my results resemble a similar, though smaller, series of analyses made by Professor C. F. Chandler of Columbia University and presented to the City Department of Health a few months after the subway was opened for travel. The conclusions which Dr. Chandler drew from his analyses and the opinions which I have formed from my investigation are similar so far as purely chemical considerations are concerned.

About eighty oxygen determinations were made for the Board of Rapid Transit Commissioners. The results were remarkably uniform. The difference between the greatest amount found out of doors and the smallest amount found in the subway was .7 per cent. The average for the subway was 20.6 per cent. by volume, and for the outside air 20.71 per cent.

One of the most instructive lines of investigation was that involving determinations of carbon dioxide. It may be well to inform those persons, if any be present, who do not happen to remember the exact significance of carbon dioxide, that analyses of air for this product of respiration are useful because they afford the best index which science has yet discovered of the presence of other and perhaps injurious matters. All air contains carbon dioxide, but the amount in the free, outside atmosphere is small and comparatively constant as compared to the amount generally found in enclosed places occupied by human beings. The difference between the amount found in the subway air and in the air of the streets was an indication of the relative purity. By comparing the amount of carbon dioxide found at different times and places, it was possible to obtain a knowledge of many important facts relating to the ventilation.

The number of these analyses exceeded 2,000. They were probably accurate to about 3-100 of one volume in 10,000 volumes of air. It was necessary to make the carbon dioxide determinations with great precision because the amount was very small. So far as I am aware, this is the largest number of carbon dioxide determinations of equal delicacy ever made in connection with a practical problem of ventilation. But large as the number was, and representing, as it did, the state of the air in a great number of places, at different times and under various conditions, the data obtained are not more than sufficient to give a fairly correct idea of the information which it was desired to obtain. The results obtained confirmed the conclusions drawn from the oxygen determinations already alluded to. At no time and at no place was the amount of carbon dioxide large. The greatest amount was 8.89 volumes in 10,000 volumes of air. This was in the tunnel under Park Avenue, near the Grand Central Station, on December 27, 1905, at 6:02 P.M.

It would be interesting, if time permitted, to consider some of the many facts which a careful

study of the results of the carbon dioxide analyses has yielded. We should see that the amount fluctuates in the subway at different hours of the day and night, and that even in the streets, there is a daily, and perhaps seasonal, variation in the amount of carbon dioxide present.

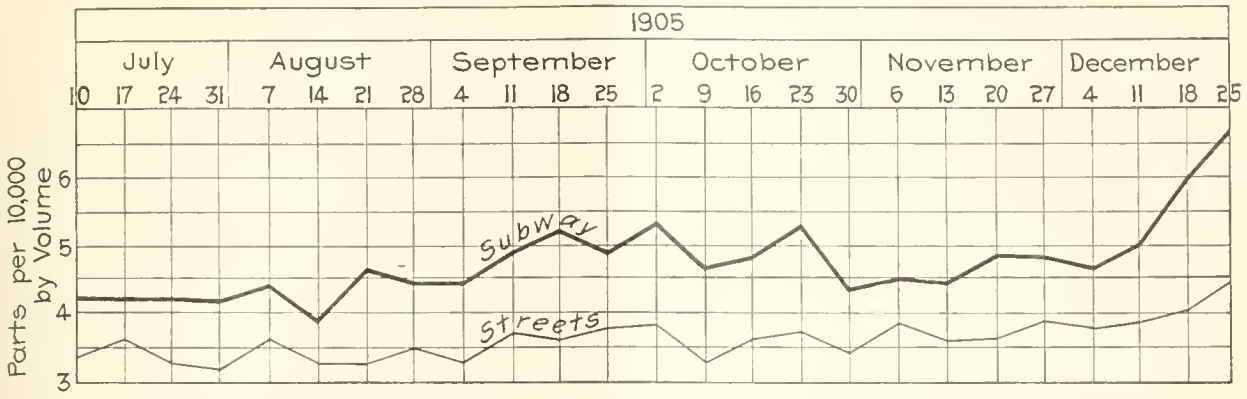

FIG. 3.—Carbon dioxide present in the air of the streets and subway.

It may be a surprise to many to know that when the trains are moving the air circulates not only in and out of the subway but from station to station with remarkable freedom, and that there is but little more carbon dioxide in the air between the stations than at the stations themselves. So great was the ventilation caused by the movement of the trains, especially the express trains, that the effects produced by large centrifugal fans and other ventilating devices experimentally employed to assist the ventilation were entirely hidden.

To physicians it will be easy to understand how the subway is ventilated. The ventilation of the subway resembles the ventilation of the lungs. Both are due to currents of air passing alternately inward and outward through certain channels as a result of changes of pressure due to the expansion and contraction of the enclosed space. It is true that in one case the size of the space is increased and reduced through the movement of its walls and in the other through what is termed a piston action, but in other respects the analogy is close. In the normal amount of air which passes out on the approach of a local train and is replaced by an indraught of fresh air as the train draws away, we have what physiologists call the tidal air. In the additional quantity which is drawn in by the express trains we have the complimental air and in the excess which is forced out by the express trains, the reserve, or supplemental air. These three, the tidal complimental, and supplemental we may term the respiratory capacity of the subway. Finally there is an amount of air which remains in the subway and is not immediately forced into the streets by any combination of local and express trains; this we may call the residual air.

As with the human body, a number of considerations control the capacity and extent of ventilation. Chief among these are the size and shape of the different parts of the enclosure and passages. The impurities are removed and fresh air is supplied to the points where it is needed by diffusion.

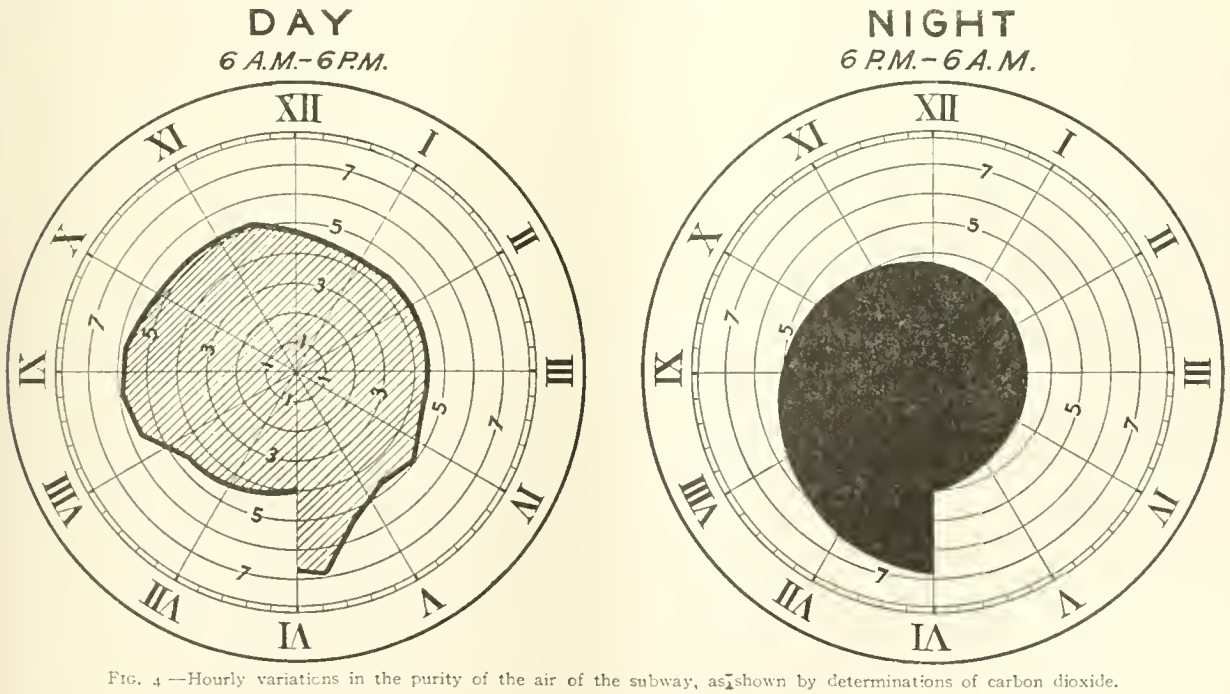

FIG. 4.—Hourly variations in the purity of the air of the subway, as shown by determinations of carbon dioxide.

Leaving now the tracing of this curious analogy between the breathing of the subway and the breathing of a human being, we will turn to the results of bacterial analyses. Studies were made of the numbers of bacteria in the air of the subway

and the air of the streets. The bacteria were collected by allowing them to settle from the air, as dust would settle, upon circular culture dishes and by filtering them from the air by means of a pump and sand filters. On being taken to the

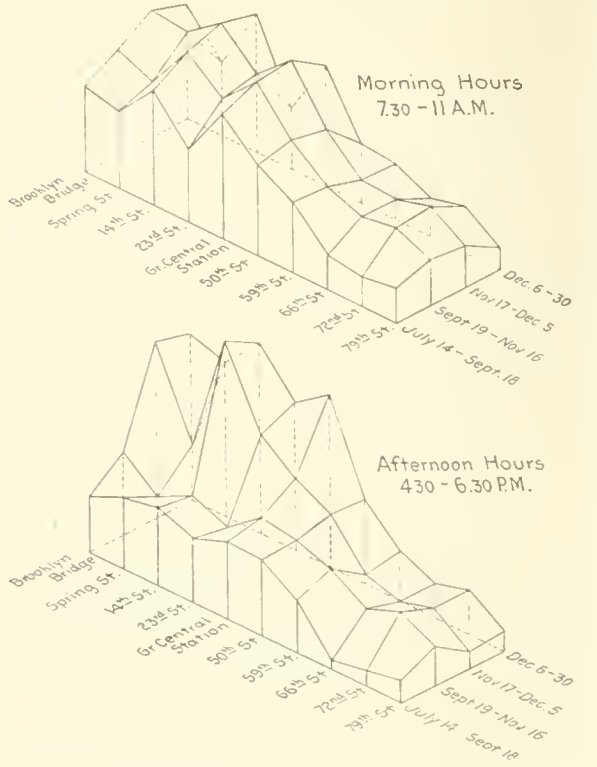

FIG. 5.—Varying degrees of purity of the subway air at different stations and at different seasons, as shown by determinations of carbon dioxide.

laboratory, the bacteria were incubated in agar at the temperature of the body for forty-eight hours. The colonies of bacteria which became visible in this time were then counted, growths of molds being considered separately. These methods proved admirably adapted to the large number of observations desired and gave a fair idea of some of the most important things to be known about the subway. About 3,000 bacterial analyses were made in all.

There were, according to averages of the results, slightly more than twice as many bacteria found in the air of the streets as in the air of the subway. During, and immediately after, rain, there were, as might be expected, fewer bacteria outside than inside, but the number increased outside a day or so after rain and was greatly influenced by the force of the wind.

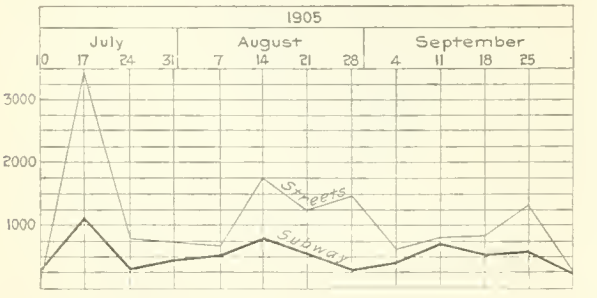

FIG. 6.—Number of bacteria, determined by the plate method, in the air of the streets and subway.

The grand average of all the results obtained with plate exposures was 500 bacteria for the subway against 1,157 for the streets. Owing to the fact that the dishes had an area of 1-15 of a square foot, these figures represent the number of bacteria which settled upon a square foot in a minute and were subsequently counted. The average number of bacteria found by filtering the air through sand filters was 3,200 per cubic meter in the subway and 6,500 in the air of the streets. It is interesting to note that the two methods agreed closely in the relation which they showed between the numbers in subway air and street air.

An important question, and one which physicians may, with special appropriateness be invited to consider, relates to the origin of the bacteria found in the subway. Are they derived chiefly from the passengers or from other sources, and what proportion of the total number are possibly pathogenic?

Little attempt could be made in the Rapid Transit investigation to identify the different kinds of bacteria and molds. To have undertaken to do so, without a great deal more time and a special corps of assistants, could have led to nothing but disappointment. By carefully collating and studying the notes which were made when the bacteria were collected for numerical analyses, and giving due weight to other considerations, I have arrived at the provisional conclusion that most of the bacteria in the subway probably came from the streets.

My principal reasons for holding this view are as follows: The numbers of bacteria in the air of the subway varied with the numbers in the air of the streets. The bacteria were more numerous in the subway near the stairways than at the ends of the stations. Dirt containing large numbers of bacteria was often seen to be carried down the stairways into the subway by the inrushing currents of air. This dirt contained far more bacteria than the dust which was of subway origin. The bacteria were more numerous on the side of the stations into which the wind blew from the street than on the opposite side. There were more bacteria at the ends of the station platforms where the trains departed than at the ends where the trains arrived.

But, although it seems likely from these reasons that most of the bacteria in the air of the subway are derived from the streets, there is excellent ground for concluding that some, and among them the most objectionable kinds, are due to the presence of people.

Aside from the danger of infection from exanthematous diseases, concerning whose mode of transmission the science of bacteriology throws but little light, it is certain that when people are closely crowded together large numbers of dangerous bacteria are transmitted from person to person in speaking, coughing, and sneezing. Against the dissemination of bacteria by these acts no restraint seems practicable. People cough and sneeze in one anothers' faces at short range and probably will do so until that distant day when high ideals of personal hygiene become a common possession. Here lies, undoubtedly, the greatest danger of subway travel, so far as bacterial diseases are concerned.

But it is by no means a danger peculiar to the subway. It exists wherever people are willing to submit to that peculiarly dense form of herding which has become a feature of city transportation.

A nearly equally common, and wholly preventable, source of dangerous pollution lies in the spitting habit. In my reports to the Rapid Transit Commissioners strong objection has been

made to the lack of enforcement of the city ordinance against spitting. This topic is so closely related to the larger subject of the kind of care which is, in my judgment, necessary for a proper sanitary maintenance of the subway, that I shall deal with it in connection with this broader question.

In my final report to the Rapid Transit Board, dated February 1, 1906, the following remarks were made: "The sanitary administration of the subway has been the most unsatisfactory feature brought out in this investigation. Inspection has shown the existence of conditions which call for immediate improvement. Stations and toilet rooms have not been kept in a clean and orderly condition. It is difficult to criticise too severely the filthy condition of the roadbed at the stations or the neglected condition of ventilation and cleanliness in some of the toilet rooms. Unless these conditions are corrected, they may very properly be regarded as suitable subjects for the attention of the Board of Health.

"The ballast at many of the stations has served as the receptacle for unlimited quantities of filth of the kind usually consigned to cuspidores. In the mater of expectoration, the guards and other employees of the operating company, who should be the sanitary guardians of the subway, are the chief offenders. It seems unnecessary to refer in further detail to this subject. The disgusting and insanitary conditions to which I refer are sufficiently evident to every passenger. I recommend that the ordinances of the Board of Health relating to spitting be enforced in the subway and that the roadbed at the stations be made clean and kept clean."

In my preliminary report to the Board, submitted October 19, 1905, I recommended that the ballast of the roadbed should be renewed at the stations, or better, replaced with a smooth, concrete surface which could easily be kept clean. The suggestions made by the Advisory Board of the Board of Health with respect to the cleaning and care of the road were strongly recommended for adoption.

A copy of these recommendations for the care of the subway was appended to my preliminary report. They seem so excellent and practical that I will repeat them here.

"The Stations.—In sweeping the station platforms and stairs of the subway, properly moistened sawdust and hair brooms should always be used. Dry sweeping should never be permitted. Suitable receptacles should be provided for the fresh and for the used sawdust and the latter should be carried off every day. The chief cleaning of the stations should be at night, immediately after the theater crowds have gone home. At this time, the stairs, station platforms and closets should not only be swept, but also thoroughly and properly mopped. They should all be scrubbed once a week at night. The sinks, urinals and closets should be cleaned with utensils kept for that purpose, at least twice daily, and afterward treated with efficient disinfectants. Dusting of the stations should be done only with moist cloths, which should be properly cleansed after each using. The use of feather dusters should not be permitted either in the stations or cars. At least four spittoons, raised from the platform and containing sawdust, should be placed in each station. These should be cleaned and disinfected twice daily. Suitable placards forbidding spitting on the stairs and platforms should be hung in conspicuous places in every station. One receptacle for papers, plainly labeled, should be placed in each station and should be emptied daily. The porters and others in charge of the cleaning of the subway stations should receive precise instructions as to their duties, and should be obliged to follow, in every particular, the methods laid down for cleaning and disinfection.

"The Cars.—The cars at the cleaning yards after sweeping should be closed, and after not less than three hours, should be cleared of the dust which has settled. This should be removed from the seats and woodwork by dry or moist cloths, frequently renewed, and from the floor by large moistened mops repeatedly rinsed in fresh water. Thorough scrubbing of the floors of the cars should be done at intervals to be determined by experience.

"A Sanitary Supervision.—There should be a special officer of the Interborough Company, expert in modern sanitation, whose duties should be not only to advise as to the methods for maintaining proper sanitary conditions in the subway and its cars, but who should be held responsible, also, for the proper execution of the methods adopted.

"The Roadbed.—It is recommended that the roadbed in front of the platforms between and at the sides of the rails should be made smooth by asphalt or some other material which can be properly cleaned. The remainder of the roadbed in the underground portions of the road should be treated with some non-inflammable material which will catch and hold the dust which may settle upon it, so that it will not be driven into the air by the passage of trains."

It is but just to say that the company which operates the subway under the supervision of the Rapid Transit Board does a good deal of work to keep the subway clean and orderly. My objection is that the work is not sufficiently well done.

Hair brooms and sawdust are used by the porters in brushing the platforms. But they are generally used in an unsuitable manner. As far as keeping the dust down is concerned, stiff brooms, without sawdust might almost as well be employed. The strong draughts are the most effective and constant agencies in keeping the platforms free of dust.

Warning signs have been erected against spitting. But no effort has been made, so far as I am aware, to have the employees of the company either call the attention of offending passengers to this warning or heed the ordinance themselves.

A contract was let to a so-called sanitary company for keeping the toilet rooms in a clean and proper condition. But this sanitary company has been allowed to violate its contract from the day the subway was thrown open to the public.

The stations have been flushed and cleaned with a hose at intervals. But these intervals have been so long that many of the employees at the stations have memories too short to remember them.

A trash gang has been employed to remove the pieces of paper and other débris from the track. But the smaller refuse, which is the most objectionable, is allowed to accumulate.

Probably the aggregate weight of dirt and rubbish removed from the stations and cars has amounted to many tons per month. But this amount could probably have been multiplied had the work been more systematically and intelligently done.

In short, as far as well cosidered, thorough methods of cleaning and sanitary care are con-

cerned, the operating company has been singularly neglectful.

It may be objected that the term "neglectful" is not a proper one to apply to this company, whose business, after all, is to carry the greatest number of people for the least amount of money. It would be curiously unlike most railroads if it gave more attention to sanitary refinements than was actually demanded of it. If anyone is inclined to make this objection, and say that the responsibility for the subway conditions should be placed elsewhere, I am quite willing to have the term "neglect" applied wherever it can be shown that it rightfully belongs.

The dust of the subway was made the subject of special study from chemical, physical, and biological standpoints. Chemical analyses of the dust showed that it contained 61.30 per cent. of iron, nearly all of which was in the metallic state. There were also 21.94 per cent. of organic matter, consisting of particles of animal and vegetable origin, 15.58 per cent. of silica and other matters insoluble in acid, and 1.18 per cent. of oil. The average of a considerable number of determina-

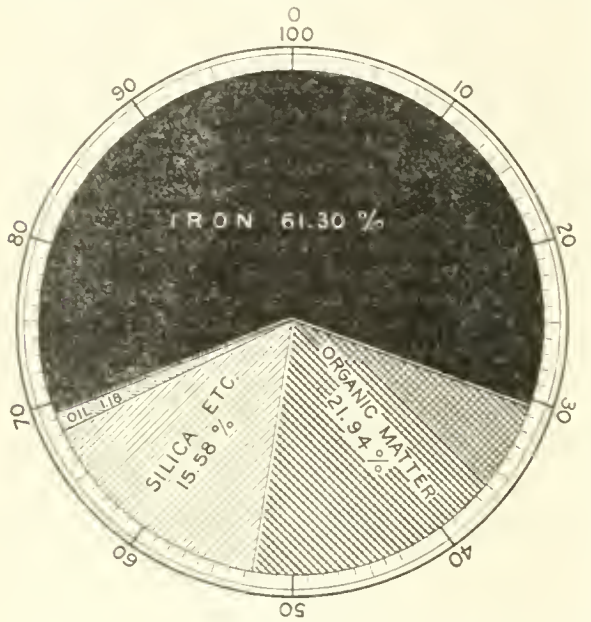

Fig. 7.—Composition of the subway dust, as determined by chemical analyses.

tions of the weight of dust suspended in the air was 61.6 milligrams per thousand cubic feet of air. The maximum weight was 204 milligrams. Twenty-three comparative tests were made to determine, with particular care, the weight of dust in the air of the subway and in that of the streets at the same time, and as near the same places as possible. These showed an excess in the subway over the outside air averaging 47 per cent. In eighteen cases, the weight of dust in the subway air over that in the air of the streets ranged from 11 to 800 per cent.

The origin of a large part of the subway dust seems fairly evident. Much of the organic matter and silica are probably carried in from the streets by the currents of air and the movements of passengers. Some is produced in the subway by the gradual wear and tear of wood and cement and other materials of construction, and imperceptible losses from such easily destructible matters as the clothing of the passengers. But all of the dust is not produced in this way. A considerable amount is pulverized metal, ground up by the operation of the trains.

It has been demonstrated that the metal in the air is chiefly cast iron derived from the grinding of the powerful brakes of the cars. It is a matter of official information that the loss in weight of the brake shoes, which are the principal wearing surfaces, has amounted to one ton per mile per month. In addition, the wheels themselves and the tracks are being constantly ground up, especially at the curves.

It must not be supposed that the great aggregate weight of metal which these figures indicate is wholly converted into dust and mingled with the subway air which is breathed by the average traveler. Many of the iron particles are too large and too heavy to be carried far, even by the strongest draughts of the moving trains. Many bits of smaller size, after being whirled about for a brief period, settle upon the oily tracks or fall into the voids in the broken stone ballast and are so retained. Only a portion of the finer particles find their way into the general atmosphere of the subway and are kept afloat by draughts.

At the same time, it is needless to point out to a body of physicians the significance which attaches to the presence of a large amount of finely divided metallic iron in the air. All text-books of hygiene, of pathology, and of medicine describe them under the terms of siderosis, pneumokoniosis, fibroid phthisis, and grinders' rot.

If any persons are inclined to believe that the amount of dust in the subway is too small to be injurious, I invite them to make a careful perusal of a recent address on "Clean Air," read by Prof. Prudden before the Practitioners' Society and published in the Medical Record, February 3, 1906.

I have advised the Board that the possibility that the metal particles in the air of the subway may produce injurious effects upon health should be thoroughly investigated.

There yet remains a single subject of general interest to refer to: The odors of the subway. No condition, excepting the heat, has caused as much personal discomfort as the odors. Yet a brief reference to them will suffice. Odors have been more or less present at all times and at all places in the subway. In some cases they have been so faint as hardly to be noticeable, while in others it has been possible to detect them on the streets over a hundred feet from the nearest opening. The odors have been most apparent during hot, damp weather, where the greatest crowding has occurred and in those parts of the subway which are most enclosed.

The cause of the most prominent odor has been the lubricating oil used on the trains. An exceedingly large quantity of this oil was used on the machinery during the first year of operation and was allowed to drip upon the ballast and ties of the roadbed.

The next principal cause of odor has been the broken stone ballast of the roadbed. This stone is trap rock which, like slate, gives off a characteristic odor when wet. On rainy days, and at those parts of the subway where the moist atmosphere has the freest access to the ballast, the peculiar, slaty odor of the stone is most pronounced.

A pungent and peculiarly unpleasant odor has been given off by a proprietary disinfectant used in the toilet rooms. Laboratory tests have shown that this compound has practically no germicidal or deodorizing properties. Its only claim for use seems to lie in its capacity to overpower other, and

possibly, less unpleasant odors. In my judgment, disinfectants and deodorants possessing an odor should rarely, if ever, be used in the subway.

Excepting in rare instances where the crowding has been excessive, and where certain employees have not been under as strict supervision as their defective sense of decency has required, the odors of the subway have not pointed to conditions directly dangerous to health.

If I were to summarize the findings and conclusions of my investigation into the narrowest possible form, I should say that I think the subway, as a whole, is sufficiently ventilated and free from conditions injurious to health, except as to the presence of metallic dust, lack of sanitary care, and conditions inseparable from overcrowding. The lack of sanitary care can, and probably will, be corrected. I do not know whether it will be necessary to do anything about the dust. If it is really dangerous, American ingenuity can certainly find a way to reduce it. I believe that investigations should proceed along the lines of doubt until no reasonable question exists concerning them.

I cannot close this brief account without expressing my sense of personal obligation to those who have assisted me in the investigation. To Professors Chandler, Prudden, Hallock, and Hiss, of Columbia University, I am indebted for valued counsel and facilities for work for which their single recompense has been my thanks. To my chief assistants, in the chemical analyses, Dr. F. J. Metzger; in the bacteriological work, Dr. C. B. Knapp, and in the meteorological studies, Messrs. Frost and Fox, I am indebted for peculiarly skillful, painstaking, and loyal service.

EXPLOSION OF A RADIUM TUBE.

By ROBERT ABBE, M.D.,
NEW YORK.

In December, 1905, I received from Hugo Lieber 50 milligrams of pure radium bromide of the strength 1,800,000, just imported from Stahmer, of Berlin, and had it transferred to a small glass tube 2½ centimeters long by 3 mm. wide, in which it was hermetically sealed after drying.

It was used daily for three months, being cleansed always by immersion in carbonic acid followed by alcohol, and always handled carefully with forceps.

On March 20, on removing it from a silver tube by a thread tied about it, it stuck in the opening of the tube and I pressed it lightly with the end of the metal forceps. Instantly it exploded with a loud report, the glass being shattered into numerous small fragments, and much of the radium was distributed against the inner lining of the tube. At the same instant I saw a cloud of pulverized radium come from the tube, as large as my hand, and rather rapidly fall to the carpet, a distance of one meter.

Laying the tube carefully on a clean sheet of paper, I made a chalk outline on the carpet within which I supposed the precious powder had fallen, though nothing of it was visible. In hopes of reclaiming it, I laid a large photographic Roentgen ray plate upon the carpet, believing it would make its impression through the double paper envelope. Only one small spot showed at the corner of the plate when developed. At night I tested the carpet with a piece of willemite, which glowed brightly at a spot some distance from the suspected area, and this spot I again tested with another photograph. The resulting plate is shown on the following page.

Every smallest grain of radium made its autograph on the plate, though only a few could be seen to glow in the dark, as they had sunk into the heavy carpet.

The atomic weight of radium is so great (342) that it had fallen within the small radius of 35 centimeters, being kept together by its heaviness. I carefully cut out the piece of carpet (after testing at a distance in all directions and satisfying myself that there was no more elsewhere) and put it and the tube in the hands of Professor Pegram, of Columbia University, to reclaim the radium, if possible.

After he had beaten it out of the carpet I again gave the photographic test and was gratified to find not an atom of radium left in it.

His careful recovery of my entire specimen is described in his own words and is worthy of record. He has again sealed it in a tube of the same size, into the end of which he fused a fine platinum wire to permit the stored-up positive electricity to discharge through it, on the theory that the negative current passes out through the glass with the beta rays. This had originally been urged upon me at first sealing by my friend Dr. Piffard, but was omitted. It may now be hoped the danger of recurrence and loss will be averted. To the original 50 milligrams recovered I gave Professor Pegram 10 mg. more to add, so that now the new tube contains 60 mg.

The danger of losing radium of so great value is not small. I quote a recent note which I have translated from the *Physikalische Zeitschrift*, Jan. 15, 1906:

"*Explosion Risk of Radium.*" By Julius Precht, Institute of Technology, Hanover.

"On Dec. 27, 1904, I sealed in a glass tube 25 milligrams of pure radium bromide, which was finely powdered and by long heat 150° C, freed of much of its water of crystallization. The little tube was used in many experimental measurements in an ice calorimeter, and, by the end of November, 1905, was brought many times into the air and warmed to the temperature of the room.

"After it had borne these handlings seven times without accident, it spontaneously exploded suddenly with a sharp report while it was lying undisturbed in a wooden dish, three minutes after bringing it into the air. The force of the explosion was so severe that the entire glass was pulverized into almost microscopic bits, while the radium bromide was to be seen in the dark, as luminous stars on the footboards of the room. This dish was entirely free from radium. Most of it lay within one meter distance from the dish, on the floor.

"The explosive character of the event implies that it resulted from a crack in the glass with a change in temperature. Otherwise larger pieces of glass would have been found in the neighborhood. The fact of the complete pulverization of the glass shows, moreover, that a great excess of pressure was present in the tube, which after-measurement showed would take 20 atmospheres to shatter.

"Radium has its own gas—either emanation or helium, which changed to 20 atmospheres pressure in the tube in the course of eleven months.

"These observations will recall the phenomenon described by E. Dorn—a spark and noise, accompanied filing of a larger tube after a half-year's rest. This electric exhibition was not observed by me, but a strong smell of ozone was observed. Mme. Curie caused an explosion by heat applied to a glass tube in which radium had been sealed for two months. That explosion occurred apparently from confined gases."

Professor Pegram writes, on restoring the new tube to me:

"The material in it consists of 24.8 mgr. radium bromide recovered dry from the broken tube, 4.0 mgr. radium bromide dissolved off the tube, 10.0 mgr. radium bromide new addition, 40.0 mgr. radium bromide (impure radium bromide) recovered from the carpet. This last 40 mgr. contains about all the radium there was on the carpet. The following process was used to obtain it: The piece of carpet was tacked over a shallow box lined with paper and drummed on until free from radium by Willemite test. A considerable amount of matter was thus beaten out and caught on the paper. In the dark the bits of radium were quite evident from their fluores-

"An attempt was made to separate the soluble radium from the dirt, which was mostly insoluble, by treatment with water and filtering. The filtrate, however, contained very little radium, from which it was evident there was enough calcium sulphate *(plaster-of-Paris dust)* present to go into solution and precipitate the radium as the insoluble sulphate.

"Accordingly, the filtrate was evaporated to dryness, the residue put back with the insoluble matter, and the whole fused with sodium and potassium carbonates. After fusion the soluble salts were washed out, leaving the radium carbonate behind with other insoluble carbonates. These were then taken up with hydrochloric acid, the excess of acid driven off from the solution, and calcium sulphate solution added.

"Some of the radium was at once precipitated as sulphate, but to complete the precipitation the solution was left on a water bath for several hours, then allowed to cool and stand for eighteen hours. This precipitate contained the radium and any barium that was present, as sulphates, and weighed 18 mgr.

"The liquid was filtered off, the filter burned and then the sulphates fused with sodium carbonate. After fusion the soluble salts were washed out and the insoluble carbonates treated with hydrobromic acid to convert into bromides.

"The result of this was radium bromide pretty free from any impurities except barium.

"In order to save all the radium, all residues and wash water had been saved. This material was again worked through the above process, and a considerable amount of impure radium bromide obtained, iron and calcium being the chief impurities. This was put with the purer product from the first separation and no further purification attempted, as it seemed more important to obtain all the radium than to risk the losses in handling and incomplete separation.

Autograph on Röntgen-ray plate, 28x35 cm. (11x14 inches), to locate 20 mg. (⅓ grain) radium on carpet.

"Throughout the work, the precipitates and residues from evaporation of solutions were examined by means of a fluoroscope consisting of a very thin layer of zinc sulphide on the underside of a piece of glass, with a lens above the glass focused on the zinc sulphide. When this was held over a layer of thorium hydroxide it was easy to see the scintillations due to the alpha rays, so with this fluoroscope it was easy to detect the presence of the slightest amount of radium or its disintegrating products in the precipitates or residues from evaporation of solutions or wash water. No material that had been in solution with the radium could be obtained entirely free from admixture of enough active material to affect the fluoroscope."

13 West Fiftieth Street

X-RAY THERAPY.*

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL, FORMERLY PROFESSOR OF ELECTROTHERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, FORMERLY ELECTROTHERAPEUTIST TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

It must be evident to any unprejudiced observer who has kept in touch with the development of radiotherapy that there has been, with but too few exceptions, little earnest effort to find out the truth about the matter.

Activity there has been without stint; too often without insight, and very often in the interest solely of self-exploitation.

In estimating the present status of the *x*-ray in medicine, I would take my stand neither among those enthusiasts who consciously or unconsciously are ever overestimating its value, nor among those ultraconservatives who without practical experience are quite ready to go to the other extreme. There are always three classes to be found in the development of any new therapy.

(1) Those who are quite honest but whose training and abilities, or whose credulity and deficiency in a healthy skepticism, render them incapable of eliminating sources of error—"who follow the lines of least resistance, believing what is easy and for personal interest to believe, and who cannot be trusted, either to observe or report their observations with accuracy."

(2) Those who are capable of sifting truth from error, but who are not quite honest; who know the truth but whose commercialism renders them antagonistic to truth.

(3) Those who are both honest and capable, who are not blinded or misled by a so-called brilliant result or two, but with analytical accuracy are able to determine the place and true value of ther own experience.

An observer† belonging to this last class who has classified and treated 167 cases of malignant disease has come to this general conclusion.

"That while the *x*-ray exerts a powerful influence upon cancer cells of all varieties, yet it is curative only in the more superficial forms of malignant disease, and should not be used in the graver and deep-seated forms of cancer except in inoperable cases, or as a prophylactic after operations, as a possible though not yet proven means of avoiding recurrence."

With these conclusions I am entirely in accord, and although my personal experience along these lines is very much less than his, limited as it has been entirely to private cases and incidental to other work, yet it has long been my thought to make some sort of use of it as my contribution to the efforts being made to establish the status of the *x*-ray in medicine.

The 17 cases that follow do not by any means represent the whole number that I have seen and actually treated, but they are the cases of statistical value so far as they go—by reason of thoroughness of treatment.

Some years ago I wrote in this wise: "As to the question of the efficiency of the *x*-ray in deep-seated and internal malignant growths, this, to say the least, must be left *sub judice*, with the burden of practical and theoretical proof in favor, if not of its inutility, at least of no signal predominating utility."

Time and added experience have not reversed the situation. On the contrary there seems less and less justification in wasting valuable time in treating any of the graver forms of malignant disease by the *x*-ray, unless of an absolutely inoperable nature.

This is, of course, very well understood by those who have had a wide practical experience, but in the minds of the laity and of very many in the profession there exists a hazy idea of the wonderful curative properties of the *x*-ray in all kinds of malignant growths fostered by sensational exploitation in the daily press, but not warranted by the facts. The few recorded cases of scirrhus of the breast, for example, or glandular sarcomatous tumors that have entirely disappeared, accordlng to reports, under *x*-ray exposure, are exceptions that simply prove the rule. The disease invariably returns as seems inevitable when we consider its constitutional character.

It is perhaps mostly forgotten that in the electrolysis of malignant tumors—popular some 25 years ago—we had very much the same experience. That electrolysis is quite as efficient in relieving the pain of various forms of cancer as is the *x*-ray was then pretty effectually demonstrated, and like the *x*-ray, *it* has in rare instances not only diminished the size of schirrus of the breast, but in one case coming under my personal observation entirely dissipated it. The electrolytic treatment in this case we administered at Bellevue Hospital in the clinic of Prof. Frank Hamilton. High hopes were entertained because of this extraordinary result, but a few months subsequently the patient returned to the hospital with malignant disease of the intestines, of which she died.

Another source of error that should be eliminated, and one, too, that is perhaps not altogether infrequent, is the tendency of hard growths simulating true scirrhus to spontaneously disappear. Just as we may have many of the objective and subjective symptoms of a true locomotor ataxia or a true ataxic paraplegia gradually disappear with recovery, so many a benign tumor has so simulated the malignant type that its disappearance under some physical method has been heralded as a triumph of the method over true cancer.

Two recent notable examples of this statement I deem worthy of record. The wife of a well known physician in this city was brought to me suffering from as well marked a case of ataxic paraplegia as had ever come under my observation and an unfavorable prognosis was given. Not a symptom was wanting, yet the patient completely recovered under the administration of certain physical methods of treatment. Evidently the pathological changes associated with true ataxic paraplegia were not present in this case; it was simply an unusual instance of simulation. The other case was one of tumor of the breast the size of a small orange, hard, painful and with slight retraction of the nipple. The patient was sent to me by her physician with the request that I use the *x*-ray. I advised against it and recommended immediate extirpation. The patient refused an operation, and her own physician began the internal administration of medicine, continued until the tumor had entirely disappeared. Whether the medicine had any influence in this resolution I cannot pretend to say, but it is quite certain that had the *x*-ray been used—to the *x*-ray would very naturally have been accredited the success. Whatever else, however, is uncertain about the case, it is quite certain that the tumor was benign and not malignant. Here, then, are two

*Introductory to a Symposium before the Medical Association of the Greater City of New York, March 12, 1906.

† William B. Coley: *Annals of Surgery*, August, 1905.

sources of error which undetected and uneliminated tend to obscure the whole subject and lead to erroneous deductions.

In treating certain forms of malignant growths again we must not lose sight of the danger of over stimulation. The analogy between the action of the *x*-ray and electrolysis in this respect has been illustrated in a number of cases in my own experience. As both methods have occasionally caused the local disappearance of pronounced malignant growths, so both have occasionally stimulated the growths to increased activity and hastened the end.

Two such results in the use of electrolysis have come under my observation, and the same number under exposures to the *x*-ray. (Cases Nos. 12 and 13.)

Singularly enough, while speaking of this the other day to a practicing physician of this city, he reminded me that he was the house physician at Bellevue years ago and had charge of one of the very cases to which reference is made, and was present at the operation.

It was a case of inoperable osteosarcoma and under electrolysis developed with amazing rapidity.

Case I.—Mrs. F., aged 49, came January 23, 1899, with a melanotic sarcoma on the left chest. In four months it had increased from the size of a marble to that of a child's fist, with widespread extensions into the axilla. It seemed to be developing more rapidly with each week and was beginning to cause considerable pain. Exposures were given every other day for two weeks, and daily thereafter with the exception of Sundays.

Later on a mild dermatitis developed, but no diminution in the size of the growth. At first the patient declared that the treatment resulted in decided alleviation of pain, but this was only temporary, and in spite of repeated exposures to the number of 32, the tumor continued to enlarge and the disease to spread and the treatment was abandoned.

Case II.—Miss S., aged 19, was first seen June 3, 1899. She was suffering from Basedow's disease —the gland enlarged to the size of a small orange and the other two cardinal symptoms well developed. Although from much previous experience, believing the galvanic current to be the most efficient form of treatment, I resolved to give the *x*-ray a trial, because of certain statements that had appeared as to its efficacy.

A month of treatment, including 16 exposures, was followed by absolutely no effect. After a rest of 30 days, for the purpose of testing any possible secondary effects of the treatment, the galvanic current was used and greatly alleviated all the symptoms, although no actual cure was accomplished in this case.

Case III.—Mr. J. C., aged 50, presented himself February 5, 1900, with carcinoma of the tongue and sublingual glands, having refused an operation and demanding the *x*-ray. Sixteen exposures were given at intervals of from two to three days—with no result with the exception of some reported slight decrease of pain. The patient then abandoned treatment, failing to keep the next appointment, and passed from under my observation. Of the ultimate outcome of the case I have no knowledge, but that it rapidly progressed to a fatal termination I have little doubt, since even during the treatment there was an appreciable spreading of the diseased area, with beginning involvement of the submaxillary glands.

Case IV.—Mrs. L., aged 41, with recurrent carcinoma of the breast, came January 8, 1901. Eight months after removal of the breast the disease returned in the scar, while in the axilla there were dense, almost immovable nodular masses. The case was now believed to be inoperable, but whether or no the patient was unalterably opposed to any further effort in that direction. She suffered more or less pain at all times, but with low barometric conditions of the atmosphere, her sufferings greatly increased, generally subsiding as the weather changed for the better. This patient received 44 *x*-ray exposures, extending over a period of three months, with no very satisfactory results. The best that can be said is that at first there was some relief of pain and no outward extension of the disease. An interesting feature of the case was that after the raying had lost its analgesic power, the galvanic current applied through clay electrodes and with a current strength as high as 50 and 75 milliamperes, kept the patient quite comfortable for many weeks. Notwithstanding the failure of the disease to further develop externally, the patient grew weaker and suddenly expired. Death was believed to be due to metastasis.

Case V.—Mrs. M., aged 45, came to me March 1, 1901, with an osteosarcoma about the size of a man's fist over the upper part of the right shoulder blade. Ten *x*-ray exposures were given during the first three weeks, resulting in some slight dermatitis. After an interval of three weeks she again resumed treatment—three times a week for ten weeks. Forty exposures were given, but with no diminution in the size of the growth. Neither had it enlarged, but the patient abandoned treatment.

Case VI.—Miss R., aged 27, came to me in July, 1902, with a well-marked case of lupus vulgaris, located on the right side of the chest immediately below the clavicle.

It began as a minute reddish blotch some ten years previously and slowly enlarged to the size of a silver dollar. While abroad the Finsen light had been used with a measure of success. Changes that were distinctly beneficial were observed up to about the fifteenth treatment, but thereafter, although there were some thirty more exposures, no further improvement was appreciable. On returning to this country some two weeks after abandoning the light treatment, she began treatment by the *x*-rays and with most satisfactory results, finally ending in complete recovery after some 45 exposures, administered through a period of four months.

Case VI.—Mr. D., aged 59, seen December 17, 1902. Epithelioma of six years' duration, located on the forehead directly over the left eye, irregular in form, measuring nearly an inch one way and somewhat less than one-half an inch the other. After six weeks of treatment and 15 rather vigorous exposures, several as long as 20 minutes, some unprotected portions of the skin approximate to the diseased part became so red and irritable that treatment was suspended for ten days. In the meantime the diseased area itself showed some improvement, and when treatment was resumed but two exposures a week were given. After a total of 57 exposures perfect healing had taken place, leaving only some redness and a little roughness to tell the site of the growth.

Case VII.—Mrs. B., aged 57, was seen January 4, 1903. Four years before a slight lesion appeared on the right side of the face, developing slowly, but causing no pain nor special anxiety. At the time she came under my observation the lesion was about the size of a silver dollar, and was readily recognized as an epithelioma. *X*-ray treatment was given every other day—sometimes every day, with occasional interruptions. A total of 45 exposures

were given with some manifest improvement in the part after the sixth treatment. After the fifteenth exposure a slight dermatitis appeared, which continued throughout the treatment, but without increasing. The healing process went on uninterruptedly throughout the course of the treatment until there was no trace of the disease. No induration was left and the surface was quite smooth, but a distinct redness prevailed for a long time.

Case IX.—Patient, a girl, aged 13, brought March 13, 1903. In this case there was a small subcutaneous nevus one inch in diameter, located on the chest immediately below the clavicle. The mother brought the case for electrolysis, but as this treatment for the superficial forms of nevi is tedious and by no means altogether satisfactory, and encouraged by the excellent result in Jutassy's well-known case, I suggested the *x*-ray. Thirty-three exposures were given through a period of four months. The surrounding healthy skin was well protected, and as the nevus was of a bright red color, it was difficult to observe any slight reaction. After the seventeenth treatment the patient complained of a distinct burning sensation over the affected area, with tenderness to the touch.

This tenderness continued for several weeks, finally disappearing with a gradual fading of the deep redness of the part and leaving the surface quite smooth and without scar, but a color considerably darker than the surrounding skin. The result was good so far as it went, but cannot be considered altogether satisfactory, since some of those interested were free to say that they would have preferred the original color. The patient, however, was not of that number.

The following case is interesting and instructive, not so much because the treatment exerted a beneficial effect on the enlarged glands, but as an evidence of an idiosyncrasy to *x*-ray influence—a condition that has been very positively denied by some.

Case X.—Miss M., aged 35, with a constitutional tuberculous condition affecting the spine, associated with enlargement of the glands of the neck. With a tube of medium penetrating power and a shield protecting the surface surrounding the two enlarged glands, the treatment was begun January 27, 1903. The distance of the tube was eight inches and the exposure five minutes. This treatment was repeated on the 31st inst., and on February 3 and 7. A new tube of somewhat greater penetrating power now replaced the old one, and in order to bring the lower part of the face, which was distinctly nodular, within the field of exposure, the shield was dispensed with. Exposures were given on February 12, 15, 19 and 24. With the exception of some slight itching no effect had been observed, but on the morning following the last application an intensely active and painful dermatitis suddenly developed. Aside from indicating a marked susceptibility to the effects of the *x*-ray, this case is a strong argument in favor of the cumulative theory of *x*-ray action. In no other way, it seems to me, than by this combination of idiosyncrasy and cumulative action, can we explain the fact that after carefully conducted *x*-ray exposures for one month with no preliminary symptoms, a violent and persistent dermatitis appears without a note of warning. It remains to say, that even this brief treatment was more or less effective in reducing the local pathological condition. The deposits along the angle of the lower jaw entirely disappeared, while the glandular enlargement decreased perceptibly in size.

Case XI.—Mrs. McE., aged 46, was sent to me for post-operative treatment in March, 1903. It was a case of scirrhus of the breast which had been removed a few months before. Twenty-five exposures were given, varying in duration from 10 to 30 minutes. More than three years have now elapsed since the operation, and a recent communication from her physician tells me that as yet there is no evidence of any return. It can only be said that the report is encouraging.

Case XII.—Mr. A. D. C., aged 70. Carcinomatous growth of considerable size on the left side of the neck. It had been removed, but had rather promptly returned, and as it involved the deeper structures his physician regarded it as in a sense inoperable and referred him for *x*-ray treatment. From November 11, 1903, to January 8, 1904, 24 exposures were given. The treatment administered was vigorous, the exposures being lengthened many times to 30 minutes, and during the last seances with tubes of great penetrating power, and yet it was impossible to excite the slightest reaction. No benefit accrued nor effect of any kind excepting a seemingly more rapid development, which both his physician and myself were inclined to attribute to overstimulation.

The treatment was discontinued January 8, and within a week the patient died. It is interesting to note that up to the time of the discontinuance of treatment there was no special decrease in strength. He came regularly to the office from out of town without apparent effort. Within a week, however, after the discontinuance of treatment he took to his bed and within a few days died of exhaustion.

Case XIII.—Mr. B., aged 50, with a large carcinomatus growth on the right side of the neck. First seen April 27, 1904. Two operations having been performed, the growth returning after each, he was referred to me for *x*-ray treatment. Twenty-five exposures were given, not only without result in retarding its progress or alleviating pain, but with very positive evidence of stimulation. During this time the patient's strength kept good, enabling him to come each time from out of town for treatment. After its discontinuance the disease continued to spread and suppurate, until in a few weeks he suddenly passed away.

Case XIV.—Mr. G., aged 37. Some two years before the beard began to fall out on the right side of the face until a circular patch of about an inch became entirely bare and smooth. Carefully protecting the surrounding healthy skin, *x*-ray treatment was begun June 7, 1904, and repeated from two to three times a week. Great care was taken to avoid a dermatitis, which might prove more annoying to the patient than the disease itself. The seances were therefore short, never more than ten minutes, and as a rule not much exceeding five. At the end of a month, and after ten exposures, the treatment was interrupted for three weeks. After that 12 more exposures were given, and treatment again interrupted partly because of some redness and irritation of the part. It was not resumed, as neither during the course of treatment nor after were there any evidences of improvement.

Case XV.—Mary J., aged 36, came to me February 18, 1905, with a lupus erythematosus on the left cheek. The disease began six years before as a small red patch, which gradually developed until nearly one-third of the face was covered by dark, repulsive looking crusts, rather firmly adherent. There was considerable itching, but no ulceration and very little pain.

The patient was treated for four months and at first we were somewhat encouraged. After ten

treatments, averaging from 10 to 15 minutes duration each, a slight dermatitis of the surrounding skin developed, and there was some clearing up of the crusts of epidermis. From this time forward, however, there was no improvement. The few crusts that had fallen off formed again and at the end of four month and after 36 exposures, the condition of the face remained about the same as at the beginning of the treatment.

Case XVI.—Mr. J. D., aged 64, was sent to me May 10, 1905, with a well-developed carcinoma of the mouth, involving the right cheek and gum. The tube used was of leaded glass, except at the end of a projection which the patient held in his mouth, thus enabling the rays to be directly localized on the diseased area.

There was very little pain, only a sense of discomfort, over which the treatment seemed to have no influence. Between May 10 and July 8, 25 exposures were given, varying in length from 10 to 20 minutes, with absolutely no effect, either good or bad, upon the morbid process.

Case XVII.—Mr. W., aged 65, came September 27, '95, with a chronic rheumatoid arthritis with synovial effusion. In addition to other methods, 40 hot air treatments had been given, together with a course of treatment by the static spark, the wave current and high frequency current, but without the slightest result. Now, the patient was desirous of trying the *x*-ray. The tissues were enlarged, soft and bulging on either side, due evidently to serous effusion. Usually there was little if any pain, and the patient could walk with almost ordinary facility. It was only occasionally that the joint became stiff and painful. After 24 exposures, administered every other day, each of 10 to 18 minutes' duration, there was no result, not even the slightest reaction, and the test was pronounced a failure.

Summary.—Melanotic sarcoma, one case; 32 exposures, no benefit.

Osteosarcoma, one case; 40 exposures, no benefit.

Epithelioma, two cases; 45 and 47 exposures, respectively; recovery in both.

Basedow's disease, one case; 16 exposures, no benefit.

Carcinoma of tongue, one case; 16 exposures, no benefit.

Carcinoma of mouth, one case; 24 exposures, no benefit.

Carcinoma of the neck, two cases, with 24 and 25 exposures, respectively; no benefit; on the contrary both were stimulated to increased activity of growth.

Alopecia areata, one case; 22 exposures, no benefit.

Lupus vulgaris, one case; 45 exposures, recovery.

Lupus erythematosus, one case; 36 exposures, no benefit.

Tuberculous glands, one case; decided benefit, but treatment abandoned because of sudden and severe dermatitis.

Scirrhus of the breast, one case; 24 post-operative exposures; no evidence of return after three years.

Rheumatoid arthritis, one case; 24 exposures, no benefit.

Nevus, one case; 36 exposures, with recovery.

In estimating a remedy it is important that we know its weakness as well as its strength, and therefore in preparing this paper my object has been, while taking due notice of both successes and failures, to emphasize the failures more than is generally done, on the principle that as much can be learned ofttimes from the last as from the first.

Every failure which is published in detail is in one way as much a fact for science as a success, since it reduces and guides the labors of future experimenters.

That the failures greatly outnumber the successes, simply indicates that in the majority of cases we have not rightly adapted the means to the end, and emphasize the proposition with which we began, that while the *x*-ray is not only valuable, but curative in many superficial diseases, both benign and malignant, it possesses but little, if any, permanent efficiency in the deeper seated and graver forms of malignant disease.

616 Madison Avenue.

MEMORANDA ANENT THE TREATMENT OF GANGRENE IN THE DIABETIC.*

By HEINRICH STERN, M.D.

NEW YORK.

Of all the complications of diabetes there is none more dreaded than gangrene. On this occasion it may practically be immaterial for us whether diabetic gangrene, so-called, is an affection *sui generis*, that is one peculiar to the diabetic, or whether it is a senile gangrene complicated by diabetic phenomena or, finally, whether the self-same causes may not stand at the bottom of both, the diabetic as well as the gangrenous processes. Enough the concurrence of these morbid states, and be the one or the other or both ever so slight and illy pronounced, it is *prima facie* evidence of a greatly depraved condition of organism. The physician as well as the surgeon appreciates the seriousness of the associated conditions, and either is loath to give a decided opinion as regards the ultimate result of the treatment he has instituted. As a matter of fact, diabetic gangrene is a state of affairs with which the practitioner, and be he ever so conservative a physician or so radical an operator, wishes not to be confronted any too frequently. Of course, there cannot be any contention about the mode of treatment when the gangrenous process is far advanced, as only by surgical interference may yet the life of the patient be spared for a while. The preeminent questions at issue: When to operate and when to treat by conservative methods, concerns all the instances in which the gangrenous degeneration is limited in extent and virulence, hence, practically all cases, when they are first brought to our notice.

We may distinguish at least two principal forms of gangrene in the diabetic: the one, concurring almost always with more or less pronounced angiosclerosis, seems to be the effect of arterio- or phlebosclerosis, and an eventual subsequent thrombosis, while the other appears to be the result of the activity of virulent microorganisms upon tissues vitiated by deficient nutrition and autotoxic processes.

Of course in the second variety endarteritic and endophlebitic changes are quite as frequent as in the first type of the affection, which, however, bears an apparent idiopathic character, while the former is more or less of a secondary or tertiary nature. The first variety, which in advanced instances can not always be discriminated from the second form, I encountered relatively oftener, in my own patients than in consulting practice in which, on the other hand, I have most always met with diabetic ulcerations, furuncles, carbuncles, and gangrenescent phlegmons, in short with gangrenous processes of bacterial origin. The cause of this fact, I think,

*Read at the meeting of the North Side Medical Society, December 21, 1905.

may be readily adduced. In diabetics, in whom the intake of carbohydrates does not exceed the tolerance for the latter, the hyperglycemic condition as a rule is likely to be reduced or to cease altogether. However, a nourishment abounding in proteids, as it is indicated in diabetes, is apt to aggravate the arteriocapillary fibrosis, which concurs so frequently even in the milder form of the diabetic process.

Thus the endarteritic and endophlebitic degeneration may continue until the lumen of the smaller vessels is obliterated and local death—especially of the distal ends of the extremities—ensues. The majority of instances of diabetic gangrene of the idiopathic type, that have been brought to my notice, occurred in individuals in whom the diabetic syndrome, having more or less vanished on dieting, was overshadowed by the syndrome of angiosclerosis.

On the other hand, I have seen almost all cases of gangrene taking their origin from inflammatory conditions in persons suffering either with grave diabetes, in whom exclusion of carbohydrates could not materially diminish the hyperglycemia, or in individuals affected with mild or moderately severe diabetes, who had never properly executed an antidiabetic regimen. These are the cases which have often been neglected, in which the diabetic syndrome is the preeminent anomaly, and which are usually referred to the consultant when the systemic decline has far progressed. Blood, lymphatics, and tissues of these diabetics, overcharged with glycose, nitrogenous excrementitious substances, and acid principles, offer a suitable soil for the display of bacterial virulence.

Without desiring to enter into statistics on this occasion I wish to state that, in my experience, the frequency of well-developed idiopathic gangrene of the diabetic was extremely small, not surpassing 1 per cent. of all the cases under observation. Of course, the gangrenous processes due to bacterial invasion, which I have seen in diabetics, were greatly more numerous, having been present, I should say, in about 10 per cent., or even 12 per cent., of all diabetics who consulted me. However, sight must not be lost of the fact that in many cases advice was only deemed necessary when the gangrenescent character of a phlegmon, etc., or the progressive tendency of a gangrenous process had become evident.

For the relative frequency of the diabetic phlegmon tending to become gangrenous, patient as well as physician, by neglecting to institute antidiabetic treatment and hygienic means, are often to blame. The infrequent occurrences in my practice of idiopathic, as well as progressive gangrene, I ascribe to the prophylactic expedients to which I resort as soon as the condition of the patient seems to necessitate them.

Prophylactic Treatment.—The ounce of prevention is worth many pounds of cure, as far as it concerns gangrene in the diabetic. Once for all, it should be understood that the best prophylactic is and remains the suppression or reduction of the diabetic syndrome. This is accomplished almost entirely in well-nigh every instance by proper dieting. The diet should conform to the needs of the organism, but should not remain one-sided for protracted periods. It is much better to have the patient adhere to rigid dieting one week in every month, than to have him pursue a strict regimen for many months, after which everything, and in whatever amounts, is allowed him. Hand in hand with the attempt at the suppression of the hyperglycemic condition a special hygienic treatment should be instituted. First and foremost, the patient's work has to be adjusted to his diminished resistance and vitality. This pertains in the same degree to mental as well as physical labor. Obesity should be reduced by exercise and gymnastics, and emaciation be ameliorated by the addition of absorbable fats of high melting point. The heart should be looked after and treated, if necessary. The best heart tonic is absolute rest in the recumbent position. Two or three weeks of absolute rest, during which time the amount of liquids to be imbibed is limited to physiological needs, are of more benefit to an overworked or weak heart than a year's stuffing with strychnine, digitalis, iron, nitroglycerin, and their likes. A great deal of attention should be devoted to the hygiene of the skin. Absolute cleanliness of the entire integument should be insisted upon. A mild antiseptic soap may be habitually employed. The body should never be immersed into cold water, but a sponge bath of cold water is permissible. Two or three times a week a warm bath of from 100° to 120° F. should be insisted upon. If the patient is obese, or if the heart displays symptoms of weakness, a daily bath of that temperature should be prescribed. The slightest abrasion of the skin, the most trifling injury from a fall, from a jerk or from cutting a corn, should be treated by strictly antiseptic methods. The body should be well protected against atmospheric influences. It is best to employ woolen underwear and stockings in winter. The heat should be equally distributed over the entire trunk, but hands, and especially feet—the latter the most frequent seat of the gangrene—may be kept extra warm. A daily moderate perspiration around the toes indicates that they are not threatened by local gangrene.

The foregoing simple measures, apart from those which apply to the heart alone or to obesity, which should be employed in the pertaining instances only, ought to be instituted in every case of diabetes coming for treatment. In cases even when the acetone bodies are present repeated attempts should be made to keep the glucose contents of the diabetic organism at a minimum.

Besides these measures I make use of some other expedients to avert the onset of idiopathic gangrene in the diabetic. This idiopathic gangrene occurs, as we have seen, in patients whose diabetic affection has not made very pronounced inroads on the general condition; in other words, in persons whose diabetes is either of a mild nature, or who have pretty well kept up antidiabetic treatment. I have never seen idiopathic gangrene in the diabetic supervening before the fiftieth year of life, and as it always concurs with angiosclerosis, the symptoms of which are usually more prominent than those of diabetes, I am forced to look upon it as a type of senile gangrene. Accordingly I treat the angiosclerosis and its complications with a view to prevent the gangrene.

I consider every diabetic a fit subject for antiangiosclerotic treatment, whose radial pulse pressure is above 150 mg. Hg. (v. Basch's sphygmomanometer) even if a hypertrophic state of his heart and the accentuation of the second aortic sound are as yet not plainly discernible. It is in such cases of latent or incipient arteriosclerosis that treatment will do most good. The antidiabetic diet, of course, should be continued, but carbohydrates in limited amounts are to be allowed. Especially should this be the case with milk which is a very acceptable and bland nutriment. Blandness of the nourishment, by the way, seems more important in

the diatetic treatment of the arteriosclerotic diabetic than the total exclusion of farinaceous material. Preparations of salts of iodine in increasing doses, should be administered for protracted periods. Circulation and metabolism in general should be stimulated as much as possible by physical means. Severe pains in thigh and calf and foot are to be considered rather the result of the endarteritic processes and incipient thrombosis than a phenomenon of "rheumatism," " gout," "neuralgia," or "diabetic neuritis." Such pains, especially if they are of nightly occurrence, and tearing or burning in character, and do not disappear on the exhibition of salicylates and other coal tar derivatives, I dare say are pathognomonic of the progressive obliteration of the lumen of the arterioles. They should not be wrongly interpreted, for the reason that a rational management of the affected peripheral parts of the extremities—almost always of the lower ones—may yet effect amelioration of the endarteritic process. In the presence of the aforedescribed pains the administration of iodine should be insisted upon. There is no consensus of opinion as to the modus operandi of preparation of iodine in angiosclerosis; possibly it is the altered viscosity of the blood, ensuing after the administration of iodine or its vasodilating properties, to which may be ascribed any beneficial influence. The best preparations of iodine to be taken for protracted periods I think are the sodium iodide, and the iodine-formic acid solution (Stern's solution) devised by me. The mechanicothermic means for the local angiosclerotic process, in the first instance, should be aimed toward stimulation and acceleration of the venous circulation. The patient may take short walks, but must not stand on his legs for any length of time Hot footbaths applied daily and followed by brisk massage of the entire limb, or the entire body, will greatly stimulate the return circulation. Still better service may be rendered by dry hot air. The affected limb should remain in the hot air apparatus at a temperature of from 250° to 300° F. for almost half an hour. (On this occasion it must be remembered that the thermometers which some manufacturers attach to their hot air apparatuses—for obvious reasons—are made to read twenty-five and more degrees higher.) It is advisable to proceed with the "bake" twice a day for no less a period than two or three weeks. Each séance may be ended with massage or if possible vibratory massage. The high frequency current has proved of special value in stimulating the local circulation, and in overcoming venous stasis. In phlebosclerotic edema the employment of the high frequency current may also be accompanied by gratifying results.

Treatment of Fully-Established Gangrene.—The management of fully established gangrene in the diabetic cannot be undertaken according to iron-clad rules. Every case demands its special study and care. Some of the lesser lesions, as gangrenescent furuncles, for instance, often heal after institution of a rigid antidiabetic diet and the repeated injections of iodine into the suppurating skin gland. Carbuncles will mostly yield to the same simple surgical means—although much slower—as are usually applied to these deep-seated inflammations of the subcutaneous tissue in the non-diabetic, provided a strict antidiabetic regimen is adhered to. Necrosis of the skin may also be cured if the glucose contents of the blood have been reduced to a minimum and the lesion is treated antiseptically. Some years ago I have seen in the Home for the Aged and Infirm, in Yonkers, a diabetic woman of sixty-five, whose entire palmar surface of one foot was a mass of necrosed tissue; after six weeks of moderate antidiabetic dieting and application of chlorine water (U. S. P.) the skin necrosis had completely subsided.

Antidiabetic treatment will almost always prove a powerful agent in assisting in the healing process of gangrenous conditions which have arisen on the basis of a diabetic cachexia. This is specially the case where such treatment was never before executed in a proper manner. In idiopathic gangrene, on the other hand, when the patient is quite robust and in a pretty fair state of nutrition, when, in other words the diabetes does not exist in a very pronounced form, antidiabetic dieting, as a matter of course, will scarcely avail anything worth while. It must not be forgotten that such patients very often are, or have been, under a rigid diet, and that their well-being, considering it from the standpoint of diabetes, leaves very little to be desired.

Idiopathic gangrene in the diabetic is always of the dry, the aseptic variety. It seems to be entirely due to insufficiency of blood supply. In this form of gangrene, the necrosed tissue becomes mummified, in which state it offers no suitable soil for the propagation of the streptococcus pyogenes or other putrefactive microorganisms. If suppuration ensues, it occurs at the place of union of the dirorganized and the living textures. The line of demarcation is normally composed of granulation tissue. Progressive gangrene is of the same nature in the diabetic as in other individuals, but of still greater virulence. It is a moist, septic gangrene. The lesion of the integument in this form of gangrene is no measure of the range of destruction in the deeper textures. The gangrenous process advances speedily along the connective tissue. Septic gangrene is ushered in by a chill, and is accompanied by progressive septicemia throughout its entire course. According to Koenig's dictum it should be the endeavor of the attendant to convert septic gangrene into destructive processes of an aseptic nature. We should aim to keep dry gangrene in a dry state and to stop the inflammatory and decomposition processes in humid gangrene, which would make it approach the dry form. The latter would be accomplished by permitting the contents of blisters to escape, by removing necrotic skin when covering a moist gangrene, and by making broad incisions and cutting out the gangrenous material when a phlegmon is present.

Dry gangrene, according to the same authority, may be kept in *statu quo* or obtained from humid gangrene by applying iodoform gauze and admitting air, and by avoiding moist dressings, even though they be saturated with antiseptics.

Although I have seen complete recoveries from gangrenescent processes on the application of moist dressings, as, for instance, the case treated with chlorine water just alluded to, I fully subscribe to Koenig's recommendations, as their execution during the last nine or ten years has given me, on the whole, quite satisfactory results.

If a case has been grossly neglected, or if the institution of an antidiabetic regimen (almost useless, as we have seen in many instances of idiopathic gangrene) cannot cause demarcation, or arrest the progress of the gangrenescent inflammatory condition, the radical operation, that is, amputation of the affected limb, must be thought of. Before amputation, which undoubtedly is the only chance of prolonging the life of a certain class of patients, is resorted to, the attending physician should lay before himself the following two questions:

First. Is the patient in a condition to be operated upon?

Second. How "high up" shall the operation be performed?

The first question really comprises the prognosis of the case under consideration; that is, will the patient live longer when the operation is performed or left undone? My answer would be that the patient may be operated upon with success:

a. When the general condition does not point to advanced cachexia.

b. When the condition of the heart is still fair.

c. When the amount of urinary glucose does not exceed 100 grams in the twenty-four hours.

d. When acetone bodies—if at all present—occur in small amounts only.

e. When the smallest possible amount of a general anesthetic, or when a local anesthetic is to be used.

f. When the operation is to be performed with due deference to even the most minute antiseptic precautions.

g. When the amount of blood to be lost is presumably small.

h. When exarticulation, which does not necessitate severance of thick layers of muscles and opening of the marrow cavity, is to be performed instead of amputation.

There is little hope for success, that is for survival of the patient:

a. When the general condition is pronouncedly cachetic.

b. When general septicemia is pronounced.

c. When the heart is failing rapidly.

d. When there exists great intensity of the glycosuria.

e. When coma is threatening, or has already supervened.

f. When progressive gangrenous processes have ensued in more than one limb.

g. When a "high amputation" is to be performed.

The second question, "How high up shall the operation be performed?" puts us in a dilemma. It goes without saying that the higher up one operates, the more effective will be the cure, but at the same time the greater will be the shock to the much deteriorated organism; and *vice versa*, the lower the point of operation the less the shock to the system, but the greater the probability of the progress of necrosis above the stump. Out of this state of affairs, in which the alternatives seem equally undesirable, the answer to the previous question, "Is the patient in a condition to be operated upon?" may give some practical suggestions.

From the standpoint of rational conservatism, I would advocate for the general run of cases—if febrile, immediate operation; if non-febrile, a waiting period, if possible, of from one to three weeks, during which antidiabetic treatment which may cause demarcation of the gangrenous process is to be executed. In case elevation of temperature should ensue during this period, an operation should be resorted to at once. As to the place of operation, I would recommend, if the gangrenous condition is limited to one or two toes, exarticulation of the parts thus affected; if more toes, or the palmar or dorsal portion of the foot, or the entire foot, or ankle, or calf, exarticulation at the knee; if pulsation of the popliteal artery has ceased, operation above the knee.

Summing up these principal points dwelled upon in the foregoing we find:

1. That we must discriminate between two forms of gangrene which may supervene in the diabetic, the idiopathic and the gangrenescent inflammatory variety.

2. That idiopathic gangrene in the diabetic does not depend so much upon the glycemic as upon the arterio- and phlebosclerotic conditions in the organism, and that inflammatory gangrene is the result of the activity of virulent microorganisms upon tissues vitiated by deficient nutrition and autotoxic processes.

3. That idiopathic gangrene was not encountered oftener than in 1 per cent. of all diabetics under personal observation, while gangrenous processes due to bacterial invasion were diagnosed in 10 per cent. or 12 per cent. of cases met in consulting practice.

4. That idiopathic gangrene may ensue in persons who have undergone, or are still undergoing, antidiabetic treatment, and who are quite robust and in a fair state of nutrition, and that gangrene taking its origin from inflammatory conditions, mostly supervenes in diabetics, who are either affected with a grave form of the disease or in whom a proper dietetic and hygienic antidiabetic treatment had never been executed.

5. That, after all, the best prophylactic of gangrene in the diabetic is the suppression or reduction of the diabetic syndrome.

6. That, together with the attempt at the suppression of the hlperglycemic condition, an abortive hygienic treatment should be instituted.

7. That, besides such measures, some additional expedients have to be resorted to in the presence of angiosclerosis, as this is the apparent forerunner of the idiopathic type of gangrene.

8. That every diabetic is a fit subject for antiangiosclerotic treatment whose radial pulse pressure is above 150 mg. Hg., even if a hypertrophic state of his heart and the accentuation of the second aortic sound are as yet not plainly discernible.

9. That the management of a fully established gangrene in the diabetic cannot be undertaken according to iron-clad rules.

10. That lesser lesions, as grangrenescent furuncles, carbuncles, and skin necrosis, will often heal after institution of an antidiabetic regimen and antiseptic local measures.

11. That idiopathic gangrene in the diabetic is always of the dry, aseptic form, and that progressive gangrene in the diabetic, as in non-diabetics, is of a moist, of a septic nature.

12. That with the means at our disposal we should aim to keep dry gangrene in a dry state, and to convert humid gangrene into the dry variety.

13. That idiopathic, aseptic, dry gangrene should not be immediately treated by radical measures, but time, during which the patient is under a diabetic regimen, should be allowed for the formation of the line of demarcation.

14. That, for a short period, an antibiabetic regimen should be instituted in cases of gangrenescent inflammations of non-febrile character before a capital operation is to be performed, but that an operation should be *immediately* resorted to at the slightest elevation of temperature.

15. That a radical operation may prolong the life in septic cases of progressive gangrene, provided the patient is in a fit condition to undergo such a procedure.

16. That there is little to be expected from an operation when the patient is in a very low state of vitality, when general septicemia is pronounced,

when the heart is rapidly failing, when there exists glycemia of great intensity, when coma is threatening or has already supervened, when more than one limb has become gangrenous, or when a "high operation" is to be performed.

17. That exarticulation is to be given preference to amputation.

65 East Seventy-sixth Street

LARYNGEAL EDEMA.*

By HARMON SMITH, M.D.,

NEW YORK.

ASSISTANT SURGEON MANHATTAN EYE, EAR, AND THROAT HOSPITAL, CONSULTING LARYNGOLOGIST MUHLENBERG HOSPITAL, PLAINFIELD, N. J.

As the history of the following cases will materially bear upon subsequent remarks, I take the liberty of briefly relating them first.

I. Two summers ago a newspaper reporter, Z. H., twenty-six years of age, came into Dr. Chappell's clinic at he Manhattan Eye, Ear, and Throat Hospital with this history: He had had the diseases of childhood, also infrequent colds, and sore throat. He does not drink, but smokes on an average four cigars daily. Five days before he had attended a banquet at which he had smoked several large cigars, and afterward he had noticed for the first time a "pricking" sensation at the root of his tongue. Later in the evening he felt a swelling of his larynx, accompanied by headache and dysphagia, but by little dyspnea. On the following day, after a sleepless night, the conditions were worse, and upon consulting the family physician he was instructed to put ice on the throat externally, and to gargle frequently with a potassium solution. On the next day the pain was more intense, the dyspnea very annoying, and swallowing was accompanied by extreme pain. His condition grew worse, so that for three days before entering the hospital he was able to swallow food and water only with extreme difficulty. On July 25, five days after the initial disturbance, I examined his throat and found his pharynx congested and the tonsils enlarged. The epiglottis was very much swollen and edematous, nearly obscuring a vision of the larynx, but what could be seen of the arytenoids, the interarytenoid space, and ventricular bands was red and edematous. The patient could only whisper, and could barely open his mouth. This fact made me look for quinsy, or some other peritonsillar condition to explain it, but I found nothing of this sort. Dyspnea was marked, the tongue furred, and the breath foul. Externally there was considerable swelling and tenderness of the submaxillary glands, more marked on the left side. Temperature 100.6°, pulse 118. There was some sweating, and a general appearance of septic absorption. Not being able to localize the lesion to which I could reasonably attribute the disturbance, I determined to deplete the edema by internal medication. Two minims of croton oil were given, followed by half an ounce of a saturated solution of magnesium sulphate every hour until free evacuation was accomplished. In addition the patient was placed under a tent where a kettle was steaming with compound tincture of benzoin, oil of pine, and creosote added to the water. Also local applications were made to the larynx of a 2 per cent. solution of cocaine and 1-1,000 adrenalin solution, and ice externally. This was kept up eight hours, with no apparent effect upon the symptoms. I then bled the patient from the median basilic vein. After this there was slight relaxation of his jaws, so that on the following day a better view of his throat above the epiglottis was obtained, and near the base of the tongue, about the height of the tip of the epiglottis, a small swelling was detected which seemed no more than the muscular unevenness occasioned by pulling the tongue more to one side than the other. Upon probing this, I detected a hard, unyielding condition, and noted it to be to the left of the median line, and that upon this same side the submaxillary gland was more tender and swollen than on the other.

The patient's temperature was now 101.4°, accompanied by sweats and chilly sensations. I attempted incision first with a curved, sharp-pointed bistoury, but owing to his jaws being nearly closed the curve was insufficient to permit of puncture at this location. I then tried a laryngeal bistoury which, after considerable pressure, penetrated a thick, encapsulated cavity from which a dram or more of dark-colored, foul-smelling pus was evacuated. The temperature dropped in eight hours to normal, and by the next day the edema had subsided so that he was able to breathe, eat, and drink with comfort. Recovery was uneventful.

Here a laryngeal edema existed with the cause temporarily obscure, location of the abscess unusual, and the patient's condition likely to necessitate a tracheotomy at any moment—for which preparations had been made. The infection had probably traveled through the lymphatics from the left tonsil, as the tumor was somewhat removed from and above the lingual adenoids. The capsule was so thick and unyielding that I believe serious difficulties would have arisen before it discharged spontaneously. His inability to swallow food had weakened him seriously, and the croton oil had irritated the bowel so that it would not retain nutritive enemas.

II. The following case is one of secondary edema, the underlying cause being a chronic nephritis. This is definitely accounted for in the autopsy report. I present the larynx, although it now shows less evidence of edema than at the time of autopsy. I. R., aged forty-four years, a cab driver. He had been a heavy beer drinker, likewise he drank whiskey undiluted. He had been on a spree for a week when I was called to see him in the afternoon of April 11, 1904. He was hoarse and breathing with slight difficulty. Temperature 99°, pulse 92. There was slight redness and puffiness of the uvula, redness of the arytenoids, and puffiness of the ventricular bands, such as is often observed in cabmen as the result of exposure and alcohol. He also had a chronic suppurative ear, with slight mastoid tenderness. Believing I would have to operate later for mastoiditis, I sent him to the Manhattan Eye, Ear, and Throat Hospital. He was given a cathartic and nitroglycerin internally. Adrenalin was given internally, as well as applied locally to the larynx. Further treatment was directed to the ear. The next morning I was informed by telephone at 8.30 that he was breathing very badly, and was cyanotic. Preparations were made for an immediate tracheotomy, and I hastened to the hospital, reaching there in ten minutes. The operation was performed at once, without anesthetic, but to no avail. Following is the autopsy report, submitted by Dr. Zabriskie, the pathologist: The face, mucous membrane of mouth and tongue markedly cyanotic. The heart dilated, valves patent. Walls of right ventricle flabby, thickened to about three-fourths of an inch. Muscles show fatty degeneration. Aorta shows a number of slightly raised, whitish-yellow calcareous plaques. The pleural cav-

* Read before the Section on Laryngology, New York Academy of Medicine, January 24, 1906.

ities contain three ounces of yellow, clear fluid. Both lungs are edematous and congested. Cut surfaces are smooth and the bronchi contain large amounts of frothy yellowish fluid; there are no evidences of consolidation. The trachea and larger bronchi show evidences of edema. The mucous membrane is red in color, thickened, and shows in spots small petechial hemorrhages. The entire larynx, epiglottis, and opening into esophagus show an enormously thickened mucous membrane. The epiglottis is three-eighths inch thick. The thickening of the ventricular bands approximates their two surfaces and closes the chink of the glottis. The mucous membrane is smooth and glistening, with no necrosis. The spleen is small, bluish-red in color. The cut surface is granular, and the pulp is easily expressed. The left kidney is small, the capsule is slightly adherent. The cut surface shows a markedly granular condition of the cortex, which is thin, and the papillæ are indistinct. The liver is enlarged. The cut surface is smooth and shows fatty degeneration microscopically. The tissue from the larynx is infiltrated with serum. The vessels are distended with blood, and at points extravasation into the perivascular spaces is noted. No bacteria could be demonstrated in the tissues or any positive source of infection be determined.

III. This case is one of sudden edema in a tuberculous larynx, necessitating tracheotomy, which has been previously reported at a meeting of the Academy by Dr. Chappell. A. C., female, aged thirty-two years. She was first seen in the clinic September 19, 1904. She had suffered from hoarseness and loss of voice for three months. The right arytenoid was pyriform in shape and swollen to the height of the epiglottis. The mucous membrane was dotted with small spots of ulceration. She was treated for some months in the clinic, when she ceased her visits. She was brought to the hospital from the country on November 6, complaining of difficulty in breathing, from which she had suffered for two weeks. On her arrival she was cyanotic, and the dyspnea was alarming. In the absence of Dr. Chappell I was called in to see the case. Tracheotmy was immediately performed under cocaine anesthesia. The breathing soon became easy and the patient slept for twelve hours. She remained in the hospital nine days, at the end of which time the temperature had fallen from 101.6° on admission to 99°, and the edema had disappeared. She was then sent to another hospital, where she remained for two months, at which time the tuberculous process seemed quiescent. The tube was then removed. Since the tracheotomy she had gained over twenty pounds. It was definitely known that this was tuberculous, as both smears and cultures showed the tubercle bacilli. Since she left this last hospital nothing is known of her condition.

IV. Lastly, the following case presents many puzzling points for consideration. M. B., aged twenty-four years, oldest of eighteen children thirteen of whom are living. Mother died in childbirth. Father living. She denies any specific trouble, and examination of the lungs is negative. Six years ago she had an attack similar to the present, when difficulty in swallowing and a sensation of swelling in the throat were the chief symptoms. Twelve months after this she had another attack, when the choking and difficulty in breathing and swallowing were more intense. The present attack is about the seventh, and began about a month ago. She consulted a throat specialist at the Bellevue clinic, who gave her some medicine which she took for three weeks, without improvement. She was first seen at Dr. Chappell's clinic at the Manhattan Eye, Ear, and Throat Hospital, a week ago. She gave a history of difficult breathing and swallowing, but unaccompanied with pain. Examination of the nasal chambers revealed polypi in both, with a bluish-red edematous swelling of the left inferior turbinate. The soft palate and uvula were thickened and edematous. The lingual adenoids were pale and edematous, and the epiglottis markedly edematous and obscuring the laryngeal view. All the structures below the soft palate were extremely pale. Believing that the edema might be influenced by the iodide, which I surmised was the medicine she had been taking, she was instructed to discontinue its use and was given one grain of mercury with chalk every three hours. Upon examination five days later some reduction of the edema was apparent, but not sufficient to warrant the assertion that the iodides were in any way responsible for its existence. There are also too many points against angioneurotic edema to give this as a positive diagnosis. From the recurrent attacks and general appearance I believe that some lymph channel has been obstructed by pressure, thus causing an infiltration of the tissues. A more definite conclusion can be arrived at only by a careful and continual observation.

However indefinite, scientifically, the term laryngeal edema may appear, the fact yet remains that when confronted with its existence none of us feel too well equipped for its care. The various classifications by different writers of the etiology of the disease have not materially aided us in its practical treatment. It is interesting to know that as long ago as 1852 Sestier submitted a classification, based on 190 acute cases, that is far from inappropriate: Typical, originating in the larynx. Contiguous, proceeding from pharynx or other parts. Consecutive, as a sequel to a previous disease of the pharynx. Von Ziemssen[1] endeavors to include under laryngitis phlegmonosa all disturbances of the larynx occasioning edema, and enumerates the following conditions: Diphtheria, erysipelas, burns and scalds, traumatism, foreign bodies, all the infectious diseases, all varieties of nephritis, diseases of the heart and lungs, and compression of the blood vessels; while Sir Felix Semon[2] would materially simplify the matter by assuming that "acute edema of the larynx, edematous laryngitis, phlegmon of pharynx and larynx, erysipelas of pharynx and larynx, and angina Ludovici are all pathologically identical and represent different degrees of severity of one and the same septic process, due to the invasion of throat and neck by various pathogenic microorganisms." If this can be substantiated it will indeed simplify the etiology.

Dr. Jonathan Wright[3] in criticism of Küttner's article on this subject, apparently agrees with Semon that septic conditions of the neck differ from one another only in degree, either clinically or pathologically. He also calls attention to the fact that certain microorganisms have been shown to have a direct etiological connection with certain diseases, yet these same organisms are constantly found in concact with the human organisms under healthy conditions. Rice, in opposition to this view, does not consider acute primary edema of the larynx erysipelatous, without some external cutaneous manifestation.[4] Küttner[5] has probably chosen the best classification, which, abbreviated, is: (1) Cases of an acute infectious nature, under which he has: Primary. When the infecting virus has selected the

larynx as its port of entry. Secondary. When the infecting virus attacks the larynx in the course of already existing infective disease, as erysipelas, scarlatina, typhoid, etc.

(2) Cases of a non-infectious nature, the etiological factors being burns, foreign bodies, traumatism, colds, certain drugs, and constitutional diseases, as syphilis, tuberculosis, nephritis, etc.

We are scientifically certain that irrespective of classification all forms of edema are either serous, fibrinous, purulent, or hemorrhagic. As it has been so clearly demonstrated by Jonathan Wright[6] that a solution in the continuity of the protecting epithelium of the tonsillar crypt plays an unimportant part in the subsequent infection of the tonsil by the bacteria present, are we not warranted in attributing to the epithelium of the larynx a similar protective power, although probably less than that of the tonsil—because not in contact with such great numbers of bacteria—but sufficient under normal circumstances to protect itself? Under abnormal systemic conditions a breach in the epithelium is not necessary. Should this be so, the argument presented by Sir Felix Semon that the bacteria "gain entrance through some accidental breach of the protecting surface of the larynx" is not sufficiently clear to be given as a means of infection. Considering how few larynges are affected by edema, irrespective of the fact that the epithelium is constantly in contact with infective bacteria, we must look for some other cause—probably a change from within—which would permit their invasion. First. We may conjecture that at some time the resistance of the larynx is reduced, either from a disturbance of the vasomotor supply or from some constitutional disease which would open the way for the invading germs. Second. We might surmise that infection is produced by the presence of too great numbers of cocci for the larynx to withstand, just as it has been proven that bovine tubercle are infectious to man only when their number is so great that collectively they form a power against which the resistance of the ailmentary canal cannot contend. Third. The virulence of the same microorganism may vary at times; or, judging from the infrequency of acute laryngeal edema, it may require the combination of these three conditions to produce it. So rare, indeed, is it that Pettesohn found only eight cases of edema of the larynx in 5,161 throat and nose cases treated between April 1, 1897 and June 1, 1899. Seven of these occurred in connection with local inflammatory conditions. Edema of the true vocal cords is far more unusual, and even Morell Mackenzie, in his great work saw it only twice. Autopsies show comparatively few cases of laryngeal edema, and out of 3,887 examinatons under Virchow edema of the larynx was noted only 210 times—only forty-four of these due to *local*, and 136 to *systemic* disease. Yet to refute this large percentage of edema due to systemic conditions, Mackenzie examined the larynx in 200 cases of Bright's disease without finding a single case of edema. We may then enumerate the causes in their probable order of frequency: (1) Infection—no matter whether it be through pyogenic or erysipelatous streptococci staphylococci, or Loefler bacilli—unquestionably infection is the primary cause. (2) Secondary to abscess formation at the base of the tongue—peritonsillar or retropharyngeal. (3) Nephritis, tuberculosis, syphilis, cardiac disease, and rheumatism, if affecting the cricoarytenoid articulation. (4) Traumatism, scalds, foreign bodies, corrosive poisons, and inhalation of flame. (5) Grip, particularly in children;[7] iodides—Hopkins[8] reports a case in which twelve grains t. i. d. produced decided symptoms; aneurysm or other tumors—by occasioning venous stasis with serous effusion into the larynx. (6) Typhoid, malaria, and scarlet fever.

Pathology.—It has been scientifically determined by Logan Turner,[9] that he development of inflammatory edema of the larynx is dependent upon three factors: (1) The intensity of the inflammatory process producing it; (2) the site of the infection; (3) the anatomical arrangement of the loose submucous cellular tissue of the larynx. In proof of the last assertion, he has injected—submucously—carmine gelatin in the liquid form, thereby filling in the loose areolar tissue of the larynx proper and epiglottis with a substance which when cooled becomes set. In this way he was able to determine the areas and limitations of greatest areolar tissue. Edema, from whatever cause, is an exudation of serum into the submucous areolar tissue—the extent of this exudation being governed by the quantity of areolar tissue and its limitations. The three stages may be enumerated as (*a*) edematous; (*b*) plastic; (*c*) suppurative. The locations most frequently involved are the aryepiglottic folds, the ventricular bands, the interarytenoid space, and the anterior surface of the epiglottis.

Symptoms.—The onset, if acute, may be preceded by a chill, followed by a temperature of moderate height. Hoarseness is almost invariably present, accompanied with slight cough. Pain, if the throat is quiescent, is not a constant factor, though a sense of discomfort is experienced always, and swallowing is usually painful. Respiration is usually interfered with and is in proportion to the advance of the trouble, the inspiratory effort being the first affected. The patient is unwilling to lie flat on his back, and prefers a sitting posture; and may be noticed using the hands as a prop, thereby gaining a slight aid to respiration. There is a decided alarm expressed in the face, and a nervous tremor may be noted as a probable result of muscular tension and anxiety. The face is first flushed, and later, when difficulty of respiration is increased, becomes cyanotic. The urine is diminished, is highly colored, and may contain albumin. In some cases we are unable to determine if the albumin is the result of the edema or if the edema is the accompaniment of the kidney condition producing the albumin. The appearance of the laryngeal parts varies with the intensity of the involvement, the time of existence, and the character of the edema—whether acute, infective, or secondary to some other condition. Acute laryngeal edema is usually brilliantly red, smooth, and glistening—later becoming serum-soaked and puffy. The other forms are less intensely red, and may assume a bluish, congested appearance, as though strangulated. However, in reading over the appearance in about one hundred cases reported, one finds no invariable rule that will apply in each case. The epiglottis suffers the most in nearly all cases, and when the edema begins in the pharynx it descends rapidly to the larynx, leaving the pharynx uninvolved. The edema does not always stop with the larynx, but frequently invades the tissues of the neck, gravitates into the trachea, and even to the lungs—as is demonstrated in the trachea I present here to-night. Not infrequently a general septic condition occurs, with metastases in neighboring joints; likewise a general nervous depression which is of grave nature. This sepsis is manifested in the rigor, sweats, and high temperature following.

Treatment.—The treatment of these cases is fre-

quently of supreme moment, especially as they occur rapidly and without warning. In the acute primary involvement, cold compresses to the throat and leeches serve as external measures. Internally a brisk purgative, or even emesis, will abstract some of the accumulating serum. Pellets of ice, steam with benzoin added, adrenalin by spray to larynx, and ten drops of the same solution every hour internally are very important therapeutic agents. The hypodermic injection of one-fourth grain of pilocarpin has been advocated by Lennox Browne. Tincture of iodine locally after cocainization has also been advised. Venesection is of considerable value in these cases, and produced a favorable change in my first case, although the edema was secondary to a lingual abscess. Scarification or puncture is of unquestioned value wherever it can be accomplished; but in three of the cases coming under my care this was impracticable, as in the first the patient's jaws were so firmly set as to prevent my reaching the larynx, and in the other two a tracheotomy was imperative, so that it would have been criminal to have delayed the operation for any other therapeutic measures. Tracheotomy, while serious, should not be long delayed after the local measures have failed, as it is the ONE most effective measure. In all the cases tabulated by Rice,[10] upon whom tracheotomy was performed, only one did not recover, and he had a syphilitic necrosis of the arytenoid cartilage and died some days after the tracheotomy—probably from systemic conditions.

In those cases in which the edema is secondary to abscess in a neighboring location, the evacuation of the pus will usually result in the disappearance of the edema. Attention must likewise be directed to any constitutional disturbance underlying the edema —whether cardiac, nephritic, syphilitic, or rheumatic. There is a vasomotor neurosis known as angioneurotic edema. Osler has reported in all about twenty-nine of these cases, and classes them under the title "Visceral Complications of the Erythema Group of Skin Diseases." [11]

The peculiarities of this edema are the sudden appearance, absence of pain and temperature, the diffeernt locations involved—not confining itself to the throat—and the rapid disappearance. Quincke first described this affection as "An Acute Circumscribed Edema," and formerly it was known as Quincke's disease, but it appears that this edema is of an urticarial nature and selects the larynx as only one of its many points of attack. As most of all ills have been ascribed to malaria, so edema of the larynx has not been omitted. I am inclined to be skeptical regarding this statement.

Doubt still exists as to the exact cause of acute primary laryngeal edema, for which reason every effort should be made to obtain definite knowledge by autopsy and microscopical examination.

THE THREE-GLASS CATHETER TEST: AN IMPROVED METHOD FOR THE IDENTIFICATION AND SEPARATION OF URETHRAL AND BLADDER DETRITUS IN URETHRITIS.

BY ABR. L. WOLBARST, M.D.,

NEW YORK.

ATTENDING GENITOURINARY SURGEON, BETH ISRAEL HOSPITAL DISPENSARY; CLINICAL ASSISTANT, GENITOURINARY DEPARTMENT, NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

VARIOUS methods have been suggested from time to time to determine in cases of acute or chronic urethritis, whether the pus or shreds found in the urine passed are derived from the anterior urethra, posterior urethra, or bladder. These methods are all more or less unreliable, for the reason that they are not mechanically correct, and for the further reason that they are based on erroneous premises.

The simplest and most commonly used of these tests is the so-called Thompson two-glass test. In this test the patient passes a portion of his urine in a clean glass, and the remainder in a second glass. It is commonly declared that the first glass shows the condition of the anterior urethra, and the second glass, the posterior. At first sight this would appear to be correct, but experience teaches us that this test is extremely unreliable, to say the least, in many cases of acute and chronic conditions of the urethra. In a very acute urethritis of a few days' duration the discharge of pus may be so great that both glasses will contain cloudy urine, and yet the posterior urethra may be not at all invaded by the inflammatory process; and conversely, in a case of chronic posterior urethritis, the first glass may and usually does contain pus and shreds, and the second glass appears perfectly clear; this is explained by the fact that the first urine passed washes out the posterior urethra, and the second urine, passing over a cleansed urethra, appears in the second glass perfectly clear. One must be on his guard at all times, lest he misinterpret the findings of this two-glass test.

Another test, less commonly used, but also liable to misinterpretation, is the so-called Jadassohn-Goldenberg test. Briefly this is performed as follows: The anterior urethra is carefully washed out until the washings come out clear; this first glass shows the condition of the anterior urethra, undoubtedly. The patient next passes his urine, and it is obvious that whatever pus or shreds come out with this urine must necessarily come from the posterior portion of the urinary tract. This test, however, does not differentiate between bladder urine and the urine washed over the prostatic urethra. We are therefore at a loss to determine by this test this most important point in the diagnosis and treatment of urethral conditions.

This test has been modified to meet the objection just mentioned in the so-called four-glass test. In this test, the various steps are as follows: The anterior urethra is washed out, and the washings are contained in glass No. 1; the patient next passes about two ounces of urine in glass No. 2, this showing the condition of the posterior urethra; the patient next passes one or two ounces of urine in glass No. 3, this showing the condition of the bladder urine; the prostate is now massaged, and the patient passes his last urine into glass No. 4, this showing the condition

of the prostatic canal after massage. In this test we are asked to draw an arbitrary line between the bladder urine and that from the posterior urethra, as shown in glasses 2 and 3, without any definite knowledge or evidence of the fact that glass 3 shows the condition of the bladder, and glass No. 2, that of the deep urethra. In other words, we must take these findings for granted, in spite of the fact that the test is obviously not correct mechanically.

To remove this element of uncertainty, I have devised a method of examination, the three-glass catheter test, which, I believe, is based on mechanically sound principles, and the findings of which are liable to practically no possibility of error or misinterpretation. I have been employing it for some months in my private and hospital practice, and have yet to meet with a disappointment in the findings.

Briefly the test is as follows: The anterior urethra is washed out carefully until the washings come out clear,—glass No. 1; this shows the condition of the anterior urethra. A soft, sterile catheter of small caliber is now passed into the bladder, and the bladder contents are drawn off into glass No. 2; this shows the bladder urine plus any possible drippings from the posterior urethra, or any possible urethral detritus carried in by the catheter; the catheter *in situ*, the bladder is washed out thoroughly, until the washings come out clear; this shows us that the bladder is empty of all pus or shreds; we now inject about eight ounces of clear fluid into the bladder, and withdraw the catheter; we have thoroughly washed out the anterior urethra and the bladder. The patient now passes two ounces of the fluid into glass No. 3; this shows us the condition of the posterior urethra. We therefore have obtained mechanically the separate fluids from the three portions of the urinary tract.

If we deside to go into further detail, we may massage the prostate and have two ounces of fluid passed into glass No. 4; this will show the prostatic condition after massage.

I have been unable to find this method of examination reported in the literature on the subject, and am desirous of securing for it a thorough trial. I believe it is a decided step forward in the more certain diagnosis and treatment of urethral conditions.

24 East One Hundred and Nineteenth Street.

Tropical Splenomegaly.—W. E. Musgrave, W. B. Wherry, and Paul G. Woolley, after presenting the history of several patients, give the following clinical summary: This symptom complex, as it occurs in the Philippine Islands, shows that it is very closely related, if not identical with those forms occurring in other tropical countries, where it is variously known as kala azar, dum-dum fever, and so on. In the Philippines, as elsewhere, young people from fifteen to twenty-five years of age seem to be the most susceptible. The disease is almost invariably ushered in by an attack of remittent or intermittent fever, which clinically resembles malaria or dengue, and is accompanied by enlargement of the spleen. Recurrent exacerbations of fever at irregular intervals occur throughout the course of the disease. This fever is not influenced by quinine, and, in the Philippines, is recognized by the natives as a "cayana" or "quisig," and is held by them to be a disease distinct from malaria. The laity consider the disease a very fatal one, and often of very short duration, but more often chronic, the patient living for several or many years. The spleen usually enlarged quite rapidly, reaching its maximum size by the second or third attack of fever, and then very often no further change occurs, unless the idea of the natives is correct, that the organ grows harder. The liver may or may not be enlarged, but when it is, that change is secondary to the splenic enlargement. Jaundice, usually slight, but also well developed, is often present, sometimes even in those cases without enlargement of the liver. This fact accounts partly for the muddy, pigmented appearance of the skin and mucous membranes which is so commonly seen. There seems to be a special tendency to involvement of the mucous membranes in this disease. This is shown by the frequent gastrointestinal disturbances, conjunctivitis, and so on. The natives say that it also causes discharges from the vagina and sometimes also abortion. There is also a tendency to hemorrhages in both the mucous membranes and the skin. Three of the writers' cases had epistaxis and bleeding from the gums. One showed hemorrhages into the conjunctiva, and two, old cutaneous remnants of hemorrhages. This tendency may be explained in some cases by the jaundice. Edemas, at first transient, later more marked and persistent, are common occurrences, and are more common on the legs and face. Ascites and pulmonary congestion may also be remarked. Anemia, emaciation, and cachexia develop gradually in nearly all cases. Pain is a frequent but by no means a constant symptom. It is manifested by headache, arthralgia, and myalgias, and is apparently more common in the early stages of the disease. Clinically the condition seen in the Philippines is a fairly definite one, and is identical or closely resembles the kala azar of other tropical countries, and might from clinical findings alone be considered as a specific entity. The writers' studies in the etiology of the disease have been negative, and in view of the discoveries of Leishman and others in clinically similar conditions, it seems best, for the present, at least, to consider these cases as examples of tropical splenomegaly and to search for further etiological data.—*Bulletin of the Johns Hopkins Hospital.*

Lipoma of the Stomach.—Bénaky sent to the Surgical Society a stomach that was taken from a man sixty-five years old, who died on the evening of his entrance to the hospital. In the pyloric region of this stomach there was an oblong, sessile tumor, developed in the submucous cellular tissue. It was easily enucleable, and adhered to the mucosa at a very limited point only. There was no doubt from its appearance, its color, and its consistence, concerning its fatty nature. This was also confirmed by histological examination. The tumor was a pure submucous lipoma. Such cases are extremely rare. Hartmann, who reported this case, has been able to collect only five of the same kind in medical literature. These were cited by Cruveilher, Virchow, Tilger, and Fenwick. Tilger reported two cases, the other authors one.—*Revue de Chirurgie.*

Ocular Troubles After a Blow on the Head. Lumbar Puncture and Recovery.—M. J. Chaillous reported the case of a patient who was in the service of Morax. The patient, who fell on his head, remained for nine days in coma after the accident. When he recovered consciousness he suffered from severe headache and disturbance of vision. Fifteen days later, the headache and visual disturbances persisting, the patient consulted Morax. Examination discovered a double optic neuritis and a retinal hemorrhage of the left eye. Lumbar puncture was practised and fifteen c.c. of cerebrospinal liquid were withdrawn. Some days after the puncture the headache ceased, and ophthalmoscopic examination showed the disappearance of both the optic neuritis and the retinal hemorrhage. After every traumatism accompanied by symptoms of intracranial pressure, ophthalmoscopic examination should be practised. If optic neuritis is discovered, lumbar puncture should be made in order to reduce the intracranial pressure and to prevent the persistence of ocular troubles.—*La Presse Médicale.*

New York, April 21, 1906.

THE RELATION OF INSECTS TO DISEASE.

SINCE 1894, when Manson announced his discovery that the mosquito was the intermediate host of *Filaria bancrofti*, the interest in the relation of insects to disease has been acute. The brilliant work done on malaria, and more recently on yellow fever, has augmented this interest, but it must not be supposed that a conception of such a relation is at all recent, or even modern. Bishop Knud in 1498 noted the coincidence between the appearance of huge numbers of flies and the plague at Aarhuus, in Denmark, and Koch, during his first stay in West Africa, called attention to the fact that the negros of the Usambara Mountains had the same word, "Mbu," for both the mosquito and malaria—the disease which they acquired when descending out of their fastnesses into the lowlands.

But only within recent years has this heretofore vague suspicion been put upon a scientific basis. In the few conditions—filariasis, malaria, yellow fever, sleeping sickness, and Texas fever—in which direct transmission by the intervention of insects has been proven, we are dealing, in so far as we know the causal factors at all, with species of microorganisms which, by their biological characters of metagenesis or alternation of generations, require an intermediate host and are unable to exist for any length of time outside of the living bodies of their harborers; and in these conditions hygienic measures for protection are much simplified by the probability that insects are the only mode of transmission, and that for each disease a recognizable species of insect may be held responsible.

The problem becomes somewhat more difficult of definite solution in the large number of bacterial diseases in which the resistance and viability of the causing agent make possible dissemination directly or indirectly by any of the vast host of insects that abound in the warm seasons. The question as to the direct transmission of any of these diseases by insects must, in the light of our present knowledge, be left unanswered. Negative evidence is furnished by the experiments of Nuttall, who allowed bedbugs and fleas to suck the blood of animals which had been killed with anthrax bacilli. Immediate transference of these to live mice remained absolutely without result. Similar experiments were made by him and others with other insects, and in a great variety of infectious diseases—all with negative results. Indirect transference, however, the infection of food and other secondary agents by insects, is another problem, and much evidence has accumulated to show beyond doubt that insects of all descriptions, suctorial or non-suctorial, are too important as distributors of disease to be hygienically neglected. Yersin, in 1894, found that flies caught in the mortuary where autopsies on plague cases had been held were infected with *Bacillus pestis*. Nuttall showed, in 1897, that the same bacillus could be found in virulent form in the bodies of flies forty-eight hours after their feeding on infected material. It has further been shown beyond doubt by a number of observers that the plague organism, the cholera vibrio, the anthrax bacillus, staphylococci, and streptococci, can pass uninjured through the bodies of flies, beetles, fleas, roaches, and a variety of other insects, and appear in virulent form in their feces. Celli fed flies on *Bacillus typhosus* and recovered the bacillus in a virulent state from their feces. The same experiment was performed for tuberculosis by Spillman and Haushalter in 1897. Hoffman, in 1898, found tubercle bacilli in four out of six flies that were caught in the room of a patient recently dead of phthisis. Dewévre examined bedbugs caught in the sick room of a tuberculous patient by injecting their bodies into guinea pigs. Sixty per cent. of his inoculations were positive. Uffelmann infected a common house fly with cholera allowed it to drink from a glass of milk, and, after letting the milk stand for sixteen hours, recovered one hundred cholera colonies from each drop of milk. Pound, while recently experimenting with plague, lost a number of his control animals. Inquiry into the cause of this revealed the fact that a number of cockroaches had been able to pass from cage to cage, establishing communication between the infected and the control animals. In a recent article in the *Centralblatt für Bakteriologie*, etc., Bd. XL, Hft. 1, Hunter adds a number of facts relating to plague, and draws conclusions which might well be taken as applicable equally to diseases more common in the Western Hemisphere. Attention was very aptly called to our general neglect of this most important problem by Veeder, in a letter published in the MEDICAL RECORD for September 17, 1898, in which he described, among other things, the open sinks of our military camps during the Spanish War, where shallow trenches filled with feces and buzzing with flies were placed within a stone's throw of the mess tents, without an attempt at the protection of the food.

While much work remains yet to be done, and many facts still remain unexplained, nevertheless, even the limited number of observations at our disposal are sufficiently striking to deserve serious consideration. It is surely just to say that there is more than a probability that germs of many infectious diseases, notably cholera, typhoid fever, and even tuberculosis, are spread indirectly by insects of all varieties, and the first practical application of these laboratory facts by prophylactic medicine should be in the rapid destruction of infectious material, its isolation from flies, and, with reference to typhoid fever especially, the proper protection of food during the warm seasons.

Epizootic lymphangitis is devastating the stables of the South of Ireland, and has stopped hunting for the time. It was introduced into the country by the horses of a battery from South Africa.

ARMY MEDICAL SCHOOLS.

It has been conclusively demonstrated on several occasions during the past few years that a properly equipped and trained medical department is of the utmost service to an army in the field. But as regards the effect of these demonstrations on our national lawmakers, it cannot be said that they have served as a lesson or a warning, and Congress has not yet gotten out of the habit of bestowing favors on this branch of the Army in a most grudging fashion. True, we are not a military nation; nevertheless, it is quite universally admitted that we require a standing army for a variety of purposes. Its personnel, its equipment, and the work accomplished are acknowledged to be of the best, but to the medical department there has never been extended the same attention that has been more freely given to the other branches of the service. Hampered in many ways, is it to be wondered at that the niggardly policy maintained towards the Army surgeons met its merited deserts in the lamentable conditions prevalent during and after our conflict with Spain? It is, or at least it ought to be, universally recognized that special fitness and training are required to enable one to fulfill properly the duties of a military surgeon, but for years we have been taking our candidates from civil practice and then leaving them to gain the necessary technical knowledge in a haphazard manner. Efforts have been made within the Department itself to supply this want, and an Army Medical School was established in Washington a few years ago, in which the newly commissioned surgeons are given systematic instruction in military medicine. This school has already justified its establishment, and we have several times referred to the good work it has done and is doing. No one will deny the wisdom of founding an institution of this kind, the necessity for which was long ago recognized by other nations, and among the latter we may note the examples of Russia and of France. The latter has had an army medical school in operation since 1856. This is located at Lyons and is described in a recent article by an English army surgeon, Capt. J. C. B. Statham, in the *Journal of the Royal Army Medical Corps.*

In France the army surgeon commences his military career at seventeen and spends four years studying medicine. The purely professional part of this work is done at the University of Lyons, and the Government pays all the fees. As a recompense for this cheap education, the cadet promises to serve six years as a medical officer, or in default to pay the entire expenses of his training. In addition to their work at the university, the cadets are taught various special subjects in the school proper, including drill, riding, corps and field service duties, and after graduation they are sent to the French staff college at Val de Grace, where another year is devoted to military medicine, surgery, and hygiene. It will thus be seen that the French medical officer has about five years of combined military and medical training before he is appointed to a regiment. A few commissions are still given by open competition among civilian doctors, but this method of recruiting the service is not encouraged and will probably soon stop, for it is quite agreed that the officers who come through the Lyons Academy are better trained and better qualified for their duties. Moreover, the school and its traditions have brought about an *esprit de corps*, and this is a factor which promotes efficiency. The Government gains by this method in having a steady supply of medical officers of experience and trained in their special duties. Although there may be some objections to adopting a plan of this kind in its entirety at the present time for our American Army, it contains mank suggestive features.

A NEW ALIEN ACT IN GREAT BRITAIN.

Complaints from all quarters have been made for some time that foreigners were being admitted into Great Britain far too freely. So lax were the provisions of the old act that few had difficulty in obtaining entrance into the country. The consequences were, regarding the matter solely from the standpoint of health, that a poverty-stricken horde of individuals of unsanitary and dirty habits settled in the already overcrowded quarters of the large cities, principally of London, and assisted to accentuate the existing unhealthy conditions. Indeed, London has been made for some years the dumping ground for undesirables of all sorts and conditions. Persons have been freely allowed to make their homes on British soil who would have been rejected with the greatest promptitude by the health authorities of the United States.

The new Alien Act for Great Britain came into force on the first day of January last, and so far as can be judged from its limited trial, has had to some extent the desired effect. Its provisions are stringent, although not nearly so exclusive as those that prevail in this country. Putting on one side the sociological aspect of the question, it may be said that the working of the new English Alien Act has had the result of preventing many persons undesirable from a health point of view from undertaking the voyage, since it is understood by agents and captains of vessels carrying immigrants that unless their passengers are in a sound state of health they will not be permitted to land, but will be sent back to the ports whence they sailed at the expense of the steamship companies.

The *Lancet* of February 3 contains an article dealing with the alien question and the new Alien Act, in which some interesting facts relating to the subject are set down. It is stated that there arrived at the Port of London during the month of December, 1905, 3,315 aliens, and that during the entire year 1905 London received 42,422 aliens, or 835 a week. The methods of medical inspection in vogue at the Port of London are closely described and provide instructive reading, but space is lacking to enter fully upon this phase of the matter. Suffice it to say that the most frequent pathological condition which has been encountered since the act has been in force has been valvular disease of the heart. "Perhaps," however, says the writer of the article, "the most striking feature in connection with the passage of the act has been the disappearance of cases of trachoma among the immigrants. In fact, hardly a case of this troublesome and contagious affliction has been seen on the immigrant ships since January 1, whilst formerly cases were met with on nearly every vessel."

The majority of those who go to London with the intention of living there are Russian and Polish

Jews, or Jews from other parts of Eastern Europe. Statistics for 1904 show that of 82,848 aliens known to have settled in Great Britain 46,095 were either Russians or Poles. As is well known, Jews always congregate in cities, so that it can be easily comprehended that immigration to Great Britain simply means a further congestion of already congested city districts and is a menace for reasons both of health and of economy. Many authorities on social and sanitary matters are of the opinion that the new British Alien Act, although a step in the right direction, does not go far enough and that it might be well to copy more closely the laws of the United States with regard to restricting immigration.

THE COMPLICATIONS OF OVARIAN TUMORS.

The number of pathological conditions for which early operation is advocated is being steadily increased and the futility of delay is perhaps no more clearly shown than in the domain of ovarian neoplasms, for the complications to which ovarian tumors are liable, and they occur in a large proportion of cases, are all of a serious nature. Of these malignancy is perhaps the most important, and next in order are torsion, rupture, and suppuration. The frequency of all of these is well demonstrated in a series of sixty-three consecutive cases of ovarian tumors, excluding the simple retention cysts, which have been observed and studied by C. C. Norris (*University of Pennsylvania Medical Bulletin*, January, 1906). His conclusions confirm the advisability of early operation in all cases of ovarian tumors unless there is a strong contraindication present. For it is shown that in these sixty-three cases there were ten cases of malignancy, ten of torsion, one of rupture, and one of suppuration. In other words there were twenty-one cases (one case of malignancy being combined with torsion) which would have terminated fatally in a short time if an operation had not been done. Of the remaining forty-two cases it is of course impossible to state the probability of fatal complications if operative interference had not been adopted sufficiently early. A very favorable aspect is given to the case by the low operative mortality, which was only 3.17 per cent. for the entire series, and two of these cases were extremely septic before operation.

Some of the author's conclusions as regards the question of malignancy in ovarian tumors are of value and interest. Thus he believes that as one in every four to six cases of ovarian neoplasm is malignant, we are warranted in regarding all cases of ovarian tumors as malignant unless proven otherwise. The operative mortality of the malignant cases should not be above ten or twelve per cent., although the number of "cures" at the end of five years will be relatively small. Carcinoma will provide the largest proportion of these recurrent cases. As regards the so-called "border line" cases, Norris also considers early operation of value, although all the clinical evidences of malignancy may be present and yet the case prove benign on operation, or even the gross specimen may appear malignant until a histological examination has shown it to be otherwise. This seems to be especially true of adenopapillomata, which frequently closely resemble adenocarcinomatous papillomata in their gross and clinical features.

The large percentage of malignant cases in Norris's series may be ascribed to the very careful and extensive microscopical examinations which were made of his specimens, and the suggestion is therefore quite opportune, that a diagnosis should be based on a number of sections taken from different portions of the growth rather than from a single one. Another interesting fact brought out in this paper deals with the apparently greater benignity of the parovarian tumors. Thus among nineteen cases of the latter in this series there were no instances of malignant degeneration or other complications. Torsion, next to malignancy, seems to be the most frequent and dangerous complication of ovarian tumors, and although it occurs in a mild form more often than is generally supposed, its character and possible outcome should always be borne in mind in any given case. Taken in connection with the statistics already published by Olshausen, Leopold, Freund, Werder, and others, Norris's results should be the means of attracting renewed attention to this most important phase of gynecology.

Another Suggestion for a Combination Anesthesia.

It is quite evident that the ideal anesthetic has not been found, if we are to judge by the constant efforts to devise some method which shall be free from all objectionable features. Most of these efforts are concerned with the combination of two elements, and now we are favored with a procedure in which four are employed. H. A. Royster (*Surgery, Gynecology, and Obstetrics*, February, 1906) believes that a satisfactory effect can be gained from the use in sequence of scopolamine-morphine, ethyl chloride, and ether. He bases his claim on the fact that ether is usually considered to be the safest general anesthetic, that ethyl chloride secures the pleasantest primary narcosis, and that the preliminary use of scopolamine with morphine quiets the patient's nerves and fears and thus lessens the quantity of ether necessary to keep up a complete anesthesia. Of the superiority of ether over chloroform as a general anesthetic, there seems to be very little doubt at the present day, but there is no doubt that its administration alone, without a preliminary, is accompanied by two great objections — the distress caused in the primary stage and the length of time and the quantity required to produce the desired effect. The popularity enjoyed by nitrous oxide gas as an ideal agent for inducing preliminary narcosis has lately been more or less affected by the good results which have followed the use of ethyl chloride for the same purpose. It is claimed that the action of the latter is more agreeable, more constant, and perhaps safer. There is no need, moreover, for a complicated, expensive apparatus. The combination of morphine and scopolamine has also recently excited much comment, and under its influence alone many operations have been done, but the consensus of opinion seems to be that its value resides largely in its employment as a preliminary to another anesthetic. It not only quiets the patient and thus promotes his courage in taking another anesthetic, but it also favors a restful sleep afterwards. Care should always be exercised, however, when it is being used, as in a number of instances untoward symptoms have been observed to

follow its administration. As Royster says that he has used his method with excellent success in a series of about fifty cases, it is certainly deserving of further attention and trial.

The Smoke Evil.

A considerable number of arrests have been made for violations of the smoke ordinance and the offending owners of furnaces have been held for trial. The usual plea made by the culprits was that it was difficult or impossible to secure hard coal, a manifestly lame excuse, since it is well known that under proper methods of stoking soft coal can be used with about as little offense as anthracite. There is no prohibition against the use of soft coal, but only against pollution of the atmosphere by soft-coal smoke. The nuisance has existed a long time, apparently because the Health Commissioner neglected his duty in the matter, but now that he has begun to move against the violators of the law he should have the support of the public and judiciary. The matter is one of sufficient importance to require adequate punitive measures, and we trust that the incorrigibles will be dealt with as strenuously as they deserve.

An Attempt to Nullify the Medical Practice Law.

The Hinman Bill, regulating and legalizing the practice of osteopathy has passed the State Senate by a vote of thirty-two to twelve. It has not yet passed the Assembly, but if it does it is to be hoped that Governor Higgins will veto it. If osteopathic practitioners are as highly educated, medically, as they claim to be they should be able to pass the Regents' examination with no difficulty and thus secure an unquestionable right to practise the healing art in this State; if they are not sufficiently instructed to pass that examination they should not be allowed to practise medicine on an equality with educated physicians.

News of the Week.

Tuberculosis Exhibition in Chicago.—A tuberculosis exhibition was opened April 2, in the Chicago Public Library Building, under the auspices of the National Association for the Study and Prevention of Tuberculosis, the Chicago Tuberculosis Institute, and the Illinois State Association for the Prevention of Tuberculosis. This exhibition contains everything pertaining to the cause, nature, and effects of the disease, as well as the means now used throughout the country for its prevention and cure. The exhibition will continue for twenty-six days, during which time special lectures and conferences on tuberculosis will be held, and exhibits demonstrated. The principal conferences to be held are those on the "Outdoor Treatment of Tuberculosis," "Workers and Tuberculosis," "Tuberculosis and Charity Organizations," "The School and Tuberculosis." On April 14 a Western Tuberculosis Conference was held, over which Dr. H. B. Favill, Chicago, presided, and at which Drs. Lawrence F. Flick, Philadelphia, and S. A. Knopf, New York, delivered addresses. The Chicago Tuberculosis Institute contemplates establishing a free dispensary for the tuberculous patients in some crowded districts. It also plans an open-air day camp, an information bureau, a lecture bureau, and an experimental station.

The New York City Tuberculosis Sanatorium.—It is announced that the city's tuberculosis sanatorium which is in course of construction at Otisville, will, in about six weeks, be ready to accommodate one hundred patients in temporary quarters. The patients will be chosen from those attending the Board of Health's tuberculosis dispensary at Sixth avenue and Fifty-fifth street.

Another Tuberculosis Cure.—Cable despatches report that Dr. Ishigami, a Japanese bacteriologist, has succeeded in obtaining an antitoxin for tuberculosis which gives good results in early cases.

Society of Sanitary and Moral Prophylaxis.—At a meeting of this society held in the Academy of Medicine on April 12 the matter of legal intervention in the effort to restrict the spread of venereal diseases was discussed. Addresses were made by Dr. John A. Wyeth, Dr. E. H. Grandin, and Ex-Senator William Lindsay of Kentucky. The general opinion expressed was that legal aid should be sought in this connection only as a last resort.

Chicago Health Department Hampered in Efforts to Control Infectious Diseases.—On this subject the Chief Medical Inspector, Dr. Heman Spalding, says that "the present most serious evil which hampers the department in its efforts to control the infectious diseases is the want of intelligence or lack of conscience upon the part of some physicians in their management of these diseases. The department is called upon to disinfect premises before the infectious period has passed. If a disinfection is made while a patient is giving off infection, the department would be guilty of aiding in the dissemination of disease. If we refuse to disinfect prematurely, the doctor making the order for disinfection is placed in an unfavorable light before the family, and the latter charges either the attending physician or the department with blundering. The department has made rules for the guidance of families as to the duration of infection in cases of infectious diseases, and these rules can be safely followed by physicians. If they do so, it will be a great help in preventing the spread of infection. At the present time we have no less than twenty-five requests for disinfection from physicians, which are held up because visits to the houses showed that the patients were still desquamating or scaling from scarlet fever, and therefore not ready for disinfection."

Maine Medical Association.—By vote of the Board of Censors of the Maine Medical Association, the dates of the annual meeting have been advanced to the second week in June—June 13, 14, and 15. This change has been made so that the dates will not conflict with those of the American Medical Association, which meets in Boston during the first week of June.

Mississippi Medical and Surgical Association.—The sixth annual meeting of this association will be held at Natchez, Miss., on Wednesday and Thursday, April 25 and 26, under the presidency of Dr. J. M. May of Westside. The secretary is Dr. H. E. Connor of Brookhaven.

Pathologist at the Craig Colony.—Dr. J. F. Munson, a graduate of the Literary and Medical Departments of the University of Michigan at Ann Arbor, who has been acting as assistant

to Dr. Victor C. Vaughan during the past two years, has been appointed resident Pathologist at the Craig Colony for Epileptics, at Sonyea, N. Y.

The Sixth International Congress of Criminal Anthropology will be held at Turin from April 28 to May 3. At the inauguration ceremonies special honors will be rendered to Professor Cesare Lombroso on the occasion of his scientific jubilee. He has been made, for the time being, Professor of Criminal Authropology of the University and will be presented with an artistic and symbolical shield and a gold medal, both by Bistolfi, as well as an album of signatures. Many festivities in honor of the large number of guests expected have been planned and include a tea in the reconstructed medieval village which has been erected on the banks of the Po, and excursions in the valley of Aosta, which is a region unusually rich in points of natural and historical interest. Information concerning the Congress is to be obtained from the Institute of Legal Medicine of the University of Turin, via Michelangelo, 26.

Dr. P. Aaser of Christiania, Norway, who was to have delivered an address on the relationship between the acute infectious diseases and tuberculosis, before the International Congress at Lisbon, is only now recovering from a severe illness of nine weeks' duration which has made it impossible for him to attend the Congress.

International Medical Association for the Suppression of War.—At the annual meeting of this society held in Paris on March 21 the president, Dr. J. Rivière delivered an address calling on the physicians of the world to unite in an effort to discourage the resort to arms and to substitute for it the settlement of international difficulties by arbitration.

Bubonic Plague at Philadelphia.—Three deaths from what is reported to be bubonic plague have occurred among the sailors of the British steamship *Burnsfield* from Bombay, which is now lying off the Reedy Island Quarantine Station. Dr. Rupert Blue of the Marine Hospital Service has been sent to take charge of the three other victims of the disease now on board the vessel.

Alcoholic Beverages in Germany.—According to statistics received from Consular officers in Germany, each inhabitant of that country consumes a yearly average of six and one-half quarts of wine, one hundred and twenty-nine and one-half quarts of beer, and nine quarts of brandy. For a population of 60,000,000 people, the liquor expenditure is $672,588,000. The average for male citizens over fifteen years would be $37.36. By contrast, German expenditures for schools were $99,722,000, for working people's insurance $104,244,000, and for the army and navy $203,847,000.

Patent Medicine Bill.—The Senate Committee on Public Health has reported favorably the Stevens-Wainwright bill providing that patented medicines containing alcohol or narcotics be labeled, showing their ingredients. It has been amended by providing that the stock of patent medicines which druggists now have on hand may be sold up to July 1, 1908, providing that each package is marked to distinguish it from goods bought after the bill takes effect. The bill has also been amended by eliminating the provisions that an analysis by the State Chemist of a patent medicine shall be presumptive evidence against druggists in criminal prosecutions.

Hospital Saturday and Sunday Funds.—The distributing committee of the Hospital Saturday and Sunday Association on April 12 alloted $81,000 to thirty-nine hospitals. The largest amounts went to the Montefiore Home and Mount Sinai Hospital, each of which received a little over $8,000.

State Board of Charities.—The State Board of Charities on April 12 reelected Dr. Enoch V. Stoddard of Rochester as president and Dr. Stephen Smith of New York as vice-president for the ensuing year. The board has adopted a resolution declaring in favor of an amendment to the pending bill providing for the care of six hundred epileptics at Craig Colony, so as to provide for the separate care in buildings and localities of the male and female patients, in accordance with the conditions already existing at the colony.

Report of the Massachusetts General Hospital.—The deficit of this institution for 1905 was $23,446.07 as against $21,109.08 in 1904, but as a considerable amount of the money expended was for the construction of new buildings the annual report is considered a very favorable one. Donations during the year amounted to $415,030.20. The total number of patients treated was 5,843, of which 3,073 were free patients.

The St. Clair (Mo.) Medical Society has elected the following officers: *President*, Dr. Hugo Wangelin of Belleville; *Vice-President*, Dr. J. W. Rendleman of East St. Louis; *Secretaries*, Dr. Jas. Twitchell and Dr. C. W. Lillie; *Treasurer*, Dr. A. E. Hansin of East St. Louis.

The Charaka Club.—At a regular meeting of the Charaka Club held on April 11 at the residence of Dr. Smith Ely Jelliffe, the members of the club and guests were entertained at a Japanese dinner. The paper of the evening on Bernardo Ramazzini, an eminent Italian physician of the seventeenth century, was read by Dr. Walter B. James, who also exhibited some rare medical books, including a perfect copy of the first edition of Harvey's "De Motu Cordis et Sanguinis."

Dr. A. M. Fernandez de Ybarra of this city on March 5 delivered a lecture on "The First Written Document about the Flora, the Fauna, the Ethnology, and the Anthropology of America," before the Biological Section of the New York Academy of Sciences, at the American Museum of Natural History.

Bequests to Charity.—Nearly all of the $900,000 estate of the late Mrs. Lucy H. Boardman is to go to various religious and charitable organizations. Some of the institutions that will profit are: The New Haven General Hospital Society, which receives $155,000 for a new building and $25,000 for maintenance; Grace Hospital, $10,000; New Haven County Antituberculosis Society, $25,000; New Haven Dispensary, $10,000.

The American Mosquito Extermination Society held its third annual convention on April 11 at the New York Aquarium. The delegates present considered the question of mosquito extermination and adopted a succinct form of statement concerning the habits and varieties of mosquitos and the best means of combating their multiplication. This is intended for distribution among the members of the society.

The Study of Alcoholism.—The University of Berlin has instituted a course of lectures on the study of alcoholism. Every phase of the question is to be considered, including the influence of alcohol on the intellectual development of the young, its relation to insurance, its connection with State hygiene, and the relation of alcohol and the penal code.

The Chicago Stockyards.—At a recent meeting of the Chicago Medical Society, Dr. W. K. Jaques, formerly City Bacteriologist, accused the United States Government of contributing to those lax conditions which are alleged by Upton Sinclair in "The Jungle" to exist at the stockyards. Dr. Jaques declared that, under the present rules of inspection, meat infected with tuberculous germs can easily be passed into the public supply. No better method could be devised, he said, for breaking down an animal's resistance to tubercle bacilli than the experience through which it passes in coming from the farm to the stockyards. The only excuse, he said, that can be given for the present standard of government inspection is ignorance on the part of the public and the medical profession as to actual conditions.

Obituary Notes.— Dr. Robert C. Davis of this city died at Roosevelt Hospital on April 13, of pneumonia. Dr. Davis was forty-seven years old and had been an inspector in the Health Department for twenty years.

Dr. Milton C. Wedgewood of Lewiston, Me., died on April 9, at the age of seventy-four years. He was graduated from the Bowdoin Medical School and in 1862 became assistant surgeon in the Eleventh regiment of Maine Volunteers. After the Civil War he settled in Lewiston, where he had since resided. Dr. Wedgewood was several times president of the State Medical Association and had held numerous professional and other offices.

Dr. Charles H. Blaney of Los Angeles, Cal., died on March 31, at the age of thirty-one years. He was a graduate of Washington and Jefferson University, and a member of the class of 1894 of the College of Medicine of the University of Southern California. At the time of his death he was assistant superintendent of the County Hospital.

Dr. C. A. Snodgrass of St. Louis, Mo., died on April 6, of pneumonia, after an illness of eight days. He was Health Commissioner of St. Louis and during the past winter had been engaged in an active campaign against the disease from which he died.

Dr. Job J. Boozer of Laurens, S. C., died on April 2, at the age of seventy-three years. About a year ago he gave up his practice at Clinton, where he had been engaged in active work for over forty years. He had been president of the Laurens County Medical Association for many years.

Dr. Oscar H. Bradley of Jaffrey, N. H., died on March 29, at the age of eighty years. He was graduated from the Castleton Medical College, at Castleton, Vt., in 1851, and later received the honorary degree of M.D. from Dartmouth College.

Dr. Hugh A. McEachren of Detroit, Mich., died on April 9, at the age of thirty-six years. He was born in Canada and was graduated from the Detroit Medical College in 1892.

Dr. A. S. Elwood of Golden, Cal., died in Denver on March 26, at the age of eighty years. Dr. Elwood was born in Petersburg, Ohio, and began the practice of medicine in Monroe, Iowa, in 1857. He served through the Civil War in the Fortieth Iowa Infantry as assistant surgeon, and then returned to Monroe, where he practised until 1884, when poor health compelled him to go to California.

Dr. J. M. Black of Knoxville, Tenn., died on April 6, at the age of thirty-nine years. Dr. Black was born in Knox County, Ky., and had practised in Knoxville for fourteen years.

Dr. E. R. Wallizer of Des Moines, Iowa, died on April 5, at the age of sixty years. He gave up active practice two years ago and had been in precarious health ever since.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL COUNCIL—DOYEN'S SERUM—COLITIS—CONGENITAL SYPHILIS—CHARITY VOTING REFORM—A PROPOSED NEW HOSPITAL—PREVENTION OF CONSUMPTION—OBITUARY.

London, March 30, 1906.

Some six months hence there is to be an election of direct representatives of the registered practitioners to the general Medical Council. The British Medical Association has for some time been scheming to control the election. You will remember its electioneering proceedings have always been objectionable, and sometimes scandalous. The plan now actively going on is for the divisions to nominate candidates from which two are to be selected for the Association to push. It is a pretty scheme for the wire-pullers to engineer with an appearance of impartiality. Candidates nominated by divisions must sign a declaration that if elected they will in every way endeavor to give effect to the opinions and wishes of the Association, and also if not selected out of those nominated by divisions will not permit themselves to be brought forward against the two chosen by the executive of the Association. Thus under a pretense of a fair election the executive is determined if possible to exercise the power of the registered practitioners, and these last are so apathetic that the scheme is likely to succeed. But this is by no means the only way in which the Association seems to be growing into a danger to professional independence, and yet the reformers make no sign.

Doyen's serum has been brought before the Medico-Chirurgical Society by Drs. Alex. Paine and D. J. Morgan, who gave a summary of Dr. Doyen's work on malignant disease and related nine cases treated by his plan at the cancer hospital here, and an investigation as to the presence of *Micrococcus neoformans* in morbid growths. This organism was detected in 25 per cent. of various growths, malignant and non-malignant. A streptococcus appeared in 30 per cent. Some other microbes, were found, but 36 per cent. of the cases were sterile. The cases treated comprised those in which no influence on the progress of the disease could be observed; those in which injections were followed by pain; and some in which severe constitutional disturbance followed. In 200 animals inoculated with the serum only inflammatory reaction followed. It consequently seems that *Micrococcus neoformans* cannot be considered the cause of cancer.

Dr. Pattison gave an account of four cases in which the serum was tried. One was of cancer of the tongue in a man of sixty-eight, an inveterate smoker. He was taken to Paris and treated by Dr. Doyen with relief of pain and fetor as well as some general improvement. But a secondary patch in the alveolus of the lower jaw appeared, and death in a few months took place. The second case was in a woman of forty-eight. The uterus had been removed for malignant growth, but abdominal cancer developed with great pain and vomiting. She improved for a time, but relapsed. The two other cases presented no improvement, unless, perhaps, some relief of pain.

Other speakers mentioned that all Dr. Doyen's patients acknowledged relief of pain some risk occurred, an overdose acted like Coley's fluid, and microscopic appearances were not altered

Colitis was the subject of a paper at the Medical Society, by Dr. A. H. Caley, who considers that in some forms it is more common than is at present recognized. He discriminated between several clinical types, in some the inflammation being confined to the colon, in others being part of a general peritonitis. In chronic catarrhal colitis one form is characterized by loose mucous evacuations or periodical diarrhea, another by constipation accompanied by excess of mucus in the stools. This last might merge into the membranous form, and it is in relation with other intestinal disorders, especially of the appendix. It sometimes simulates appendicitis, particularly the chronic form. Membranous colitis is associated with chronic constipation, neurasthenia, and acute paroxysms of pain, besides more persistent local symptoms. Pericolitis spreads through the coats to the peritoneum; in the region of the cecum it is clearly the old perityphlitis. To avoid confusion Dr. Caley would distinguish between pericolitis dextra and sinistra. Ulcerative colitis formed another group, and for accurate diagnosis called for careful scrutiny of symptoms and systematic examinations of dejecta. In all forms these should be added to physical examinations of the colon.

Dr. Savill said he had found in 140 cases of neurasthenia 40 per cent. had been traceable to early colitis or other gastrointestinal disorders. He had no doubt the bowel

trouble was the cause of the nervous symptoms, for these disappeared under treatment directed to the colon.

Mr. Swinford Edwards advocated large enemata of antiseptic solutions which he found generally successful. He said the mucous membrane could be seen and applications made by the proctoscope and sigmoidoscope.

Dr. F. J. Poynton said large enemata were questionable if ulceration was suspected. Large and frequent doses of magnesium sulphate he thought the best treatment.

Dr. F. De Havilland Hall said colitis resembled the mucous disease in children described by Eustace Smith. He prescribed careful feeding, hot fomentations, and in certain cases copious enemata of weak boric acid solution.

Dr. J. J. Perkins read a paper at the same meeting on congenital syphilis and such results of the acquired disease as are amenable to medical treatment. Congenital lesions may appear in middle life or later. Fournier recorded cases at sixty. Argyll-Robertson pupil, though doubtless due to cerebral syphilis, might occur, Dr. Perkins considered, alone and apart from any general or progressive nervous disease. He insisted on the frequency of arterial thrombosis as a cause of nervous disease, and on syphilis as a cause of neuralgia and signs of pressure. High fever might be caused by syphilis, and would yield only to specific treatment. Abdominal gummatous tumors might be mistaken for malignant growths. Dr. Perkins thought he had seen amyloid disease of the kidney disappear under treatment.

Dr. Savill said Lancereaux described intermitting pyrexia in early and late cases and was confirmed by Bristowe and Murchison.

Dr. C. W. Chapman said the history of a small itching sore in the penis was a useful diagnostic indication. Dr. Pernet said that congenital syphilis might resemble that acquired in early childhood. He did not put much reliance on the history of a primary lesion in either men or women. Iodide alone was not a specific; mercury was the only true one.

Dr. Poynton, Dr. Paramore, and Dr. Dett. Hall agreed as to mercury, and the first named mentioned two cases of cretinism in syphilitics. The president, Sir L. Brunton, thought perhaps iodide did good by bringing into the incubation mercury which had been stored in the tissues, and he mentioned a case in which five-grain doses of iodide had been taken for years without effect, but on increasing it to fifteen grains recovery was rapid.

The Charity-voting Reform Association, founded in 1873, has steadily pursued its object of inducing the supporters of charities to abandon the voting and canvassing system, which involves great hardship on many hard cases and tends toward a trafficking in proxies by enthusiastic workers for individuals. The report for the past year has just appeared and enumerates some of the institutions which have adopted the reform. In most of these candidates are selected after an investigation of the claims of applicants by committees appointed for the purpose. In others contributors place their proxies in the hands of the managers or one of them. In some, as the National Hospital, the rule is adopted that any canvassing, trafficking in, or exchange of votes for those of other charities, disqualifies the candidate for whom it is attempted.

People who have money for the establishment of new hospitals are sometimes much misinformed as to the necessity of their proposed charity. A case in point is that of the late Mr. Chester, who left a sum for building and endowing a general hospital on Putney Common, where there is no need for such a charity, which would only tend to pauperize the neighborhood. A meeting of the local practitioners brought out a good deal of opposition to the scheme, and it was agreed that the most that would be useful would be a cottage hospital with a dozen beds. Moreover, that is quite as much as the legacy is likely to support, and yet there are some people who would ask the public to subscribe £20,000 for a site and buildings for such an institution. Above all, the profession is unanimously opposed to an out-patient department. If the hospital is not established within twenty years of the testator's death, which took place in 1900, the money is to go to Guy's Hospital. I would urge all interested to let it go to Guy's, where it would unquestionably do good rather than harm.

Lord Derby presided at the seventh annual meeting (on the 20th inst.) of the National Association for Prevention of Consumption. The debt has been cleared off during the year and a small balance remains. This favorable condition results from the meeting at the Mansion House, when the Lord Mayor presided and a sum of £765.80 was subscribed.

Lionel S. Beale, F.R.S., died the night before last, aged seventy-eight. He has been a great figure for many years. A long life of strenuous work in the metropolis is thus brought to a close—one may almost say a life in King's College and Hospital, of which respectively he was Emeritus Professor and consulting physician. He was born in London (in 1828) where his father was in practice, educated at King's College school and then at the King's medical department. Here he left his mark. When twenty-four years old he opened a private laboratory for original investigation and the teaching chemistry and microscopy. About a year later he was appointed to a professorship in his college—that of Physiology, from which he was afterwards transferred to the chair of Pathological Anatomy and later still to that of Medicine. This he resigned in 1896 after forty-three years of professional work. For forty of these years he was on the staff of the hospital as well. He had been Croonian lecturer to the Royal Society and Lumleian lecturer to the Royal College of Physicians, which conferred on him the Baly medal.

His works on the "Microscope," "Bioplasm," "Life, Matter and Mind" will be household words to many of your readers. The elder ones will also remember the "Physiological Anatomy and Physiology of Man" and the "Archives of Medicine," which he maintained for a considerable period. He contributed to the proceedings of the Royal Society, and to the several medical journals, and edited Todd's "Clinical Lectures."

Dr. J. M. Martin, J.P., F.R.C.S., M.D., of Blackburn, died suddenly on the 20th inst. from cerebral hemorrhage, aged fifty-eight. He had been for above twenty years Surgeon to the Blackburn Infirmary, retiring in 1904. He was educated in Edinburgh, Liverpool. He qualified in 1847, but later on added higher diplomas and degrees. His "Ambulance Lectures" passed through four editions. He took an active part in the life of Blackburn, was specially interested in the Volunteer Movement, and was Surgeon-Major in the Army Medical Reserve.

THIRD ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

WATER SUPPLIES IN THE PHILIPPINES—INFANT MORTALITY IN MANILA—MEDICAL PRACTICE IN THE MARSHALL ISLANDS—RADIOACTIVITY—MALARIA—AN EPIDEMIC OF ESTIVOAUTUMNAL FEVER.

MANILA, P.I., March 2, 1906.

THE first scientific session of the third annual meeting of the Philippine Islands Medical Association was begun Thursday afternoon, March first, at 3 P.M. The first paper read was "Some Observations on the Water Supplies in the Philippine Islands," by Dr. John D. Long, of the Public Health and MarineHospital Service, also Assistant Director of Health. He said that so far as it had been possible to determine, at the present time only six towns in the Philippines had water supplies worthy the name. He stated that the Manila water system was built by the Spaniards, the work being begun in 1880, but even while this was classed as among the towns having a proper water supply, it was far from being satisfactory, because the water-shed was inhabited and cholera and other water-borne diseases had been encountered on its slopes from time to time, and this has been one of the most serious and vexatious problems with which the health authorities have had to deal in the two cholera epidemics which have visited the Philippine Islands since 1902.

In the new system which was now under construction, the reservoir would be higher up in the Mariquina Valley, at a point above which the water shed was uninhabited, and furthermore, the Government, having secured possession of all the land above that point, would insure its remaining free from habitation. He stated that the water system which had been installed, since the American occupation, at Mariveles, afforded an excellent index of how much the public health in the Philippines might be improved if a proper water supply could be obtained. At Mariveles, before the installation of the system, water was obtained from wells, or streams that ran through the village, etc., and dysentery, diarrhea, worms, and other intestinal diseases were very common, but since the installation of the new system the old method of procuring water had been entirely done away with, and since that time intestinal diseases had practically disappeared, the death rate of the village being reduced almost one half.

If the inhabitants could be induced to boil their water, the speaker said, possibly the present crude and clumsy methods of obtaining it might be satisfactory, but, after a most vigorous campaign to bring this about, it was safe to say that even in the presence of cholera not more than ten per cent. of the people boiled their water. He stated that the natives did not like boiled water, claiming that it produced disorders of the stomach, rumblings, indigestion, diarrhea, etc. A great many analyses have been made of the water taken from surface or dug wells, throughout the islands, and they have uniformly shown

amebas or monads, or both, with a high bacterial count. Amebas had also been found in the water from artesian wells which had a depth of over 500 feet, and that this was probably due to defective construction and probably could be remedied.

Dr. Long was of the opinion that the best solution of the water problem in the Philippine Islands was the boring of artesian wells, and proposed a scheme whereby the inhabitants of each village could tax themselves ten cents per month, and while this fund was accumulating, the Government would advance them sufficient money to install their wells. That by such a method, it would only be a few years until a proper water supply might be had over the greater portion of the Islands, at least.

The next was a paper by Dr. Edwin C. Shattuck, Medical Inspector, Bureau of Health, on "Some Observations on Infant Mortality and Its Causes in the City of Manila." This paper brought out nothing particularly new. The author maintained that the causes of the very high infant mortality in the Philippines could be accounted for in the same manner in which infant mortality in other cities is brought about. He stated that the very crude manner in which obstetrics was practised by the natives probably was a factor in the production of the high mortality; that the practice of winding a rope about the abdomen below the umbilicus, crossing the ends, and having two persons pull strongly, in opposite directions, in order to aid in the birth of the child, produced lesions in the latter which gave it a very bad start in life.

Dr. C. H. Otto Bartels read a paper entitled, "Ethnological and Medical Observations in the Marshall Islands." The author gave a very interesting account of the manner in which medicine is practised in those islands, and the readiness with which the natives accepted modern medical applications.

The next paper, on "Radium and Radioactivity," was read by Professor Paul C. Freer, Director of the Bureau of Science, formerly professor of chemistry, Ann Arbor University, and was a particularly interesting review of the literature on radium and radioactivity up to the present time. He stated that Bequerel was undoubtedly entitled to the greater portion of the credit in this work, and that the credit given to M. and Mme. Curie was entirely too high. He said that as yet little had been done in the Philippine Islands upon this subject, although a number of samples of water had been examined, which were taken from near volcanoes, but up to the present time no radioactive qualities had been found. Dr. Bacon, of the Bureau of Science, had made one observation which had not been recorded heretofore, namely, that the electrometer was apparently very much affected by sunlight, from which he concluded that there must be considerable radioactivity in the sun.

The next paper, "Observations on Malaria; Latent Infection in the Natives in the Philippines; Intracorpuscular Conjugation," was by Dr. Charles F. Craig, Assistant Surgeon, United States Army; Pathologist and Bacteriologist of the United States Army Division, Hospital Division, Manila; Member United States Army Board for the Study of Tropical Diseases. He stated that his observations had been made principally about Camp Stotsenberg, in Pampanga Province, the locality mentioned being one of the most favorable in the Philippines for the study of malaria; that owing to the character of the soil, even after the heaviest rains, the ground was perfectly dry, and that no standing or stagnant water existed within a mile of the coast. He stated that he was unable to find breeding places for anopheles within a mile of the post; but, when the grass around the post was allowed to grow to any length, the mosquitos increased greatly in numbers and shortly afterwards there was also a consequent increase in malaria. That, in the 380 cases of malaria which he had observed in the past five months, he was able to demonstrate the parasite in all of them; 248 occurred in Americans, and 138 among natives; 98 were infected with the tertian plasmodia, 8 with the quartan, and 272 with the estivoautumnal, thus showing the estivoautumnal fevers to be the most numerous. He believed that the source of the disease was the latent infection among the natives, and stated that in all, 225 natives without clinical symptoms were examined, of which number 115 were found to be infected. He stated that this agreed with the recent experience of James, in India. He laid particular stress upon the fact that it was useless to attempt to rid a locality of malaria unless all of the inhabitants were treated with quinine. The process of intracorpuscular conjugation, as seen in malaria, was not a sexual act, because no difference in sexes can be distinguished in conjugating bodies, but it is a process which is very common in many classes of protozoa, and tended to preserve the reproductive powers in which it occurs. By continued division many of the protozoa eventually became exhausted, and to prevent this conjugation occurred, the two conjugants, which are not sexually differentiated, becoming one, thus bringing about a restoration of the former reproductive activity, due to rejuvenescence of the vital activities of the organism, and if it were not for this latter process, many of the protozoa would soon cease to exist.

The last paper of the day's session, "An Epidemic of Malarial Fever of the Estivoautumnal Type," was divided into three parts: the first, "Clinical Observations," by Dr. Giles B. Cook; second, "A Topographical Study of the Infected Region and the Mosquitos Found There," by Dr. Charles S. Banks, Entomologist of the Bureau of Science, and third, "A Report on the Blood Examinations and a Study of the Fatal Cases," by Moses T. Clegg, Bureau of Science. This was a brief study of an epidemic that occurred in the camps along the route of the new water construction that is now being carried on in the Mariquina Valley, and was an excellent example of a bad site having been chosen for a camp, and showed that the ordinary prophylactic doses of quinine which are recommended, namely, three to five grains, were not sufficient to protect persons who inhabited infected regions.

THE ETIOLOGY OF PNEUMONIA.

To the Editor of the Medical Record:

Sir:—In your issue of April 7, 1906, Dr. Beverley Robinson, in speaking of the pneumococcus, says: "What endows it with special virulence in certain cases we do not know." I beg to call the attention of Dr. Robinson and of others to the fact that in the *Medical News*, November 18, 1905, and in the Medical Record, January 27, 1906, I demonstrated the fact that the pneumococcus or the diplolanceo-bacillo-coccus, as I named it, in order to acquire virulence, must pass through a susceptible animal, like the house mouse; and for reasons explained in the above-mentioned articles, I consider the house mouse as the main factor in causing pneumonia. I furthermore showed, by experimental evidence, that the pneumococcus, which is our habitual host, is far from harmful, but seems to perform rather useful functions. The injection of large doses of the sputum of a tuberculous patient—who has since died of tuberculosis—into a white mouse and into a house rat, produced no effect on those animals, whereas my own sputum has always had a fatal effect on mice, and I never had any lung trouble, nor mouth trouble, not even a sore tooth.

I claim to have established the etiology of croupous pneumonia. If any one can disprove my statements, all he has to do is to come forward with facts. I really cannot see how any intelligent physician, in speaking of pneumonia, can repeat the old phrase about sterilizing the mouth, catching cold, etc., when there is absolutely no foundation in fact for it; no more than there was for the many ingenious theories which had been advanced concerning the etiology of malaria and yellow fever before the mosquito theory was established. Now their etiology is summed up in one word, "mosquito;" and I hope the etiology of pneumonia will also soon be summed up in one word, "mouse."

E. Palier, M.D.

New York.

Progress of Medical Science.

New York Medical Journal, April 7, 1906.

Remarks on Acute Intestinal Obstruction.—The histories of four cases are given by Howard Lilienthal. He notes that death from obstruction is rarely if ever due to the mere fact that the bowels do not empty themselves. It is usually due to strangulation with peritonitis in which the distention plays an important rôle. Nonoperative recovery is not an impossibility in rare cases, but we should disregard this very remote possibility and operate as soon as the diagnosis can be made. Visible peristalsis is an important indication of obstruction, while visible coils without peristalsis indicates paresis of the intestines. Hiccough and the frequent regurgitation of fluid from the stomach, even though this fluid be neutral, nonirritating, and clear, is of grave prognostic import. Gastric lavage should never be practised before making the diagnosis and laying out the plan of action.

What Causes the Pylorus to Relax?—A. L. Benedict does not believe that pyloric relaxation is due to the presence of HCl in the stomach contents, as has been asserted by Cannon and other investigators. His objections are thus formulated: (1) The local changes in reaction are physiologically inevitable. (2) The rela-

tive acidity of the chyme is not diminished by the passage onward of a small portion, yet the pylorus does not remain patulous. (3) While this failure of a conditinuous relaxation of the pylorus may be explained by the distal acidity, it is in close analogy with the action of other alimentary sphincters, which close without any exciting reflex that can be ascribed to differences in chemical reaction. (4) Fully half the stomach contents normally escape before it is conceivable that any great proportion of hydrochloric acid is present. (5) Clinical experience with dietaries shows that, other things being equal, meals that call for considerable hydrochloric acid secretion usually remain in the stomach longer than those which do not. (6) Clinical experience with stomach contents proves conclusively that deviation from the normal standard of hydrochloric acid secretion produces just the opposite effect to what would be expected if this were the cause of pyloric relaxation. Even in achylia gastrica, there is no necessary abnormality of pyloric function, certainly not in the direction of retention.

The Vasomotor Factor in Asthma.—Francis Hare says that the meaning and mechanism of many asthmatic paroxysms may be interpreted as follows: (1) hyperpyremia; (2) widespread vasoconstriction compensated for by bronchial vasodilatation, or the converse; (3) vascular distention of the mucosa of the bronchioles; (4) obstructive dyspnea; (5) exaggerated combustion (catabolic expenditure); (6) gradual dispersion of hyperpyremia; (7) cessation of the vasomotor variation; (8) subsidence of vascular distention and asthmatic paroxysm. The author says that the dyspnea of asthma depends on obstruction in the bronchioles and the obstruction mainly on vascular distention of the bronchial mucosa. In this vascular distention there are four essential factors: (1) a localized vasodilatation; (2) a generalized vasoconstriction; (3) the work done by the cardiac systole, and (4) the amount of blood in circulation. Increase of these factors increases dyspnea and vice versa. The most efficient thermal means of relieving asthmatic dyspnea is external heat combined with cold inhalations. Adrenalin is a most powerful constrictor. Nitre paper relieves by causing bronchial vasoconstriction. Amyl nitrates and nitroglycerine promote general vasodilatation. Morphine paralyzes the vasomotor system. The same is true of alcohol. Dry cupping is of great value. Emotions causing a diversion of vascular pressure may act similarly. Agencies reducing cardiac systolic action relieve asthma. Hemorrhage of any kind often affords immediate relief to the dyspnea.

The Treatment of Diffuse and General Peritonitis, with Special Reference to the Murphy Method.—J. H. Gibbon believes that the best results come from immediate opening of the abdomen, search for and removal of the cause of inflammation and thorough draining of the abdominal cavity with the least possible disturbance of the viscera. The technic of the plan followed by Murphy consists in making a small opening in the abdomen, closing the perforation or removing the appendix as the case may be, introducing a large drainage tube into the pelvis, placing the patient in a sitting posture of from thirty-five to forty-five degrees, and giving a quart of salt solution every two hours by the rectum. The abdominal contents are not mopped, washed, or handled. Saline laxatives are not employed. They only stir up a peristalsis which tends to spread the inflammation.

Journal of the American Medical Association, April 14, 1906.

Infantile Scorbutus.—Of the fifty cases analyzed by J. L. Morse, seven were developed under his own personal observation, six patients were brought to his office, nine were seen in hospitals and twenty-eight in consultation, only five of the latter having had the real nature of the trouble recognized. They were about equally divided between the sexes and nearly three-fourths were in the second half year of life. The youngest was four months and the oldest twenty-one months old. Analysis of the food showed unsuitable feeding. The lack of freshness and the heating of food seemed also to play a part. Improper diet seemed to be able to produce scurvy without necessarily impairing the digestion. There were signs of rickets in all but nine of the children, but no apparent relation existed between the severity of rickets and that of scurvy. The symptoms are analyzed in detail. The most general one was tenderness on handling. Next in frequency came paresis, followed in order by inflamed gums, swelling, hematuria, pallor, ecchymoses and hemorrhage from the bowels, mouth or orbit. Hemoglobin and number of red corpuscles were reduced in the two cases examined, and there was also a slight leucocytosis. Pain on motion of the extremities was present in forty-three cases. The hematuria cases form a special group, and this was the only symptom of scurvy in two instances and preceded the symptoms in two other cases. Blood was present in some cases in large amounts and the urinary albumin was in proportion to the blood. As regards the diagnosis, he remarks that the first symptom is usually loss of color, often associated with loss of appetite, but the first symptom to call attention is likely to be tenderness on handling, more frequently in the legs than the arms. Treatment consisted in insuring proper diet. One patient was given lemon juice. The others received orange juice, which was very effective. Lovett considers at least one tablespoonful a day as necessary and two tablespoonfuls, or the juice of half an orange, daily, ample to produce a rapid cure.

Fever in the Newborn.—W. J. Butler emphasizes the importance of the observation of temperature during the early days of infant life and discusses the literature. The chances of infection in the newborn are numerous, to-wit: By the contact of infectious material to the eyes, nose, or mouth, traumas incident to forceps delivery, unclean surroundings, or attendants, and the always-possible source of infection, the navel. He reports an interesting series of cases of infection of the respiratory tract in the newborn, the exact source of which was not demonstrable. The disease was confined to one ward in the hospital and contact transmission seemed highly probable. The symptoms were rather uniform, but not specially characteristic. The temperature was high and remittent, and there was evidence of acute rhinitis and laryngitis. In the one fatal case the child apparently died of uremic poisoning. The cases demonstrated the susceptibility of the newborn to infection of the respiratory passages and illustrated the rapidity of conveyance and briefness of incubation in infection with the *Micrococcus catarrhalis* and with the pneumococcus, and the contagiousness of what might ordinarily be called a cold. The treatment was mainly symptomatic. The treatment of this condition generally must be primarily prophylactic, strict asepsis at delivery and subsequently.

Iodine in Surgery.—J. E. Cannaday finds a sterilized glycerin or olive oil emulsion (10 per cent.) of iodoform to be a very satisfactory method of treatment of cold abscess in patients of lowered resistance. A 1 to 1,000 solution of iodine is of great value as an irrigation in uterine sepsis, suppurative arthritis, abscess cavities, empyema, boils, small abscesses, and carbuncles. After emptying and removing necrotic tissue, he uses plain official tincture of iodine. Lately he has been using a 0.5 per cent. solution of iodine for hand disinfection as a final application, and also for the operation site, with excellent results. The formula for the solution is given as follows: Iodine 2.5 gm.; potassium or sodium iodide 5.5 gms.; water 250 c.c. This can be readily diluted to any desired strength, and is very stable. He considers it the disinfectant *par excellence* for these purposes. The usual caution as to iodine poisoning is given, but he remarks that in abscess cavities and septic infection there is greater tolerance of the drug.

The Lancet, March 31, 1906.

A New Chauffeur's Fracture.—Under this title S. Raw refers to the case of a man whose car suddenly stopped. He quickly alighted but neglected to retard the starting device, and taking a light hold of the starting lever, he gave it a sudden pull, when, instead of starting, the engine fired back and he received a violent shock on the hypothenar eminence. When first seen by the author, ten days later, the man had a prominent swelling over the proximal half of the fifth metacarpal bone of the right hand. A diagnosis of fracture was made and confirmed by a skiagram, the fifth metacarpal showing a break at the point of its junction of base and shaft. The possibility of such accidents is so great and the whole subject of such present-day importance that we reproduce the author's comments entire. He notes that several cases of fracture of the lower end of the radius have been recorded as the result of firing back of motor car engines when attempts have been made to start them whilst the spark was advanced, but he has seen no case recorded in which a fracture of any other bone occurred during this manipulation. The fact that in this case it was the fifth metacarpal bone which gave way is sufficiently accounted for when the conditions under which the accident occurred and the various factors at work are considered. First, in the hurry, a tight and strong grip was taken of the starting lever, the driver's hand being passed so far round the handle that its olivary end rested on the hypothenar eminence; and secondly, the spark was so far advanced that any back-fire occurring was sure to be a sharp one and such as would allow no time for

the release of the handle. The quick recoil was therefore transmitted most forcibly through the most prominent part of the handle—namely, its olivary end—which was resting directly over the portion of bone fractured. Had a less tight grip of the handle been taken the principal effort required to start the engine would have been exerted by the thumb and index finger and therefore when the back-fire occurred one of two things might have happened—viz., either the handle would have flown from the grasp altogether, or the force would have been transmitted through the first and second metacarpal bones to the lower end of the radius, resulting in a fracture of that bone.

Tetanus After the Induction of Premature Labor.—Case reported by W. H. Gregory; his patient was a woman of forty-two years, in her eleventh pregnancy. The early months were characterized by several hemorrhages. Finally, toward the end of the fourth month a severe flooding necessitated induction of premature labor. There was no trouble with the placenta and no postpartum hemorrhage. The fetus was removed with the fingers inserted through the os. All went well for six days. On the evening of the seventh day the patient complained of stiffness in the cervical muscles. On the next morning the condition was typical. All measures for relief (including serum injections) proved futile, and death came on the fourth day from asphyxia due to spasm of the respiratory muscles. The author considers that the bacillus of tetanus must have entered the system through the placental site, as there was no tearing of the os during dilatation, and the strictest asepsis was maintained throughout the case. The patient lived in the country and there had been no cases of the disease in human beings or animals in the vicinity for years.

Primary Sarcoma of the Lung.— H. W. Webber reports the case of a man of twenty-nine years, complaining for three months of anemia and loss of strength, and sent from America to Europe for a change of air. On the voyage over he had pain in the left side and shortness of breath, considered due to pleurisy. On landing he was sent at once to a hospital. He was in extreme collapse and had a large left pleural effusion. One pint of claret-colored fluid was drawn off. He steadily failed, was tapped again, but finally died in about two weeks. Autopsy showed the stomach much dilated, the great curvature being half-way between the umbilicus and the iliac crest. The pylorus was normal, and there was no pyloric obstruction. The liver was large, friable, and fatty. There was excess of pericardial fluid and of epicardial fat. The left pleural cavity contained three pints of blood-stained fluid. The lower three-fourths of the left lung were replaced by a fleshy, nodulated, hemorrhagic growth, there being only part of the left apex remaining as lung tissue. Microscopically this was found to be a very hemorrhagic mixed-celled sarcoma.

Erythema Scarlatiniforme Sent Into Hospital as Scarlet Fever.—Two such instances occurred in the practice of J. Beard and T. W. N. Barlow. They note that in the absence of chemical and bacteriological methods of differentiation, we are often compelled to await developments before coming to a positive diagnosis. They consider that physicians in general show a tendency to rely too much upon the character of the rash and to pay too little attention to the consideration of other and equally important factors in the diagnosis—namely, the condition of the tongue (and whether that condition is in the relation which it should bear to the rash and other signs, having regard to the time which has elapsed from the commencement of the illness), the general characteristics of the throat, the character of the onset, and the past history of the individual with respect to infectious sickness, exposure to infection, age of patient, etc. The most striking point of distinction between the two conditions noted in the title is the early commencement of desquamation in erythema scarlatiniforme, which may last for several weeks and sometimes indefinitely. In the case of a person who has had previous attacks, the history is helpful, but if there is any doubt the case should be isolated. It is also very probable that some of the cases of so-called recurrent scarlet fever are really due to this disease. In conclusion, they call attention to the important points in differential diagnosis, three of which should be borne in mind—viz., the very early onset of desquamation, the desquamation taking place while the erythema is in the florid stage, and thirdly, the erythematous base observed after desquamation and which remains for some time, with its peculiar glistening and greasy appearance.

British Medical Journal, March 31, 1906.

Antidiphtherial Serum by the Mouth.—J. D. Rolleston expresses doubt as to the efficacy of this remedy by the mouth and believes that the conclusions drawn by a recent writer as to its benefits were predicated upon too few cases to be conclusive. While he is a believer in antitoxin, he maintains that there is no doubt that a certain number of diphtheria cases can dispense with the remedy without any untoward results. The value of the oral administration of antitoxin as a preventive measure cannot be gauged from so small a number of cases, especially if one considers how large a number of those exposed to infection escape an attack of diphtheria without prophylactic treatment, not only among the nursing and medical staffs of large fever hospitals, but also among the more susceptible population of younger persons. On the other hand, the value of preventive injections is well established.

Ventrofixation.—B. M. Bone's patient was a woman of forty-five years, with the hypertrophied cervix protruding through the labia. On reduction of the mass, the uterine body was found retroverted. After some preliminary treatment to build the patient up, ventrofixation was performed in the following manner: An incision was made in the median line and the uterus pushed up by an assistant from the vagina, and a No. 4 silk suture passed through its muscular wall fairly deeply; gentle traction was then made upon this, and the uterus drawn up into the wound as far as it would come. Then while still held by the suture the silk fixation sutures were passed, three in number, of No. 3 size. They were all passed in the following manner: first through the parietal peritoneum from below upward, and then over a space of about one-eighth of an inch, and then from above downward; then through the uterine tissue, and finally through the parietal peritoneum at the opposite side in the same manner as described. The suture used for traction in the first instance was passed through the skin on either side after the fixation sutures had been tied and cut short, and after the incision had been closed with silkworm this suture was tied over the gauze pad, being subsequently withdrawn on the fifth day. As she was not fit to bear the further prolongation of the anesthetic a plastic operation upon the perineum was done two months later. Recovery was uneventful and complete.

Death from Enlarged Thymus Gland.—J. Rooth's patient was a boy of eighteen months, subject to attacks of dyspnea almost from birth, of the nature of laryngismus stridulus. Enlarged tonsils and adenoids were found, but the child died before the day set for operation. On opening the thorax a large thymus was found, embracing the bifurcation of the trachea and weighing one ounce and six drams (average weight, two drams). Its length was three and one-half inches. The spleen was of the same measurement and weight of the thymus; no evidences of rickets and no deposits of lymphoid tissue other than those noted. Two theories as to the cause of death in such cases have been advanced, the toxic and the mechanical. Considering the small space between the manubrium and vertebræ in a child and the intimate relation of the thymic mass to the innominate arteries and veins, cardiac auricles, and trachea, the mechanical theory presents no difficulties, the author thinks; in three cases in which death has come from some shock (young adults in whom the status lymphaticus is present), toxic agencies may also be a factor. Some cases of death from "overlaying" are, in the author's view, undoubtedly due to the status thymicus, and many women are therefore wrongly accused of suffocating their infants.

The Prognosis in Posterior Basic Meningitis.—The study of O. Hildesherm is based upon 133 cases. Of this number 43 were sent out of hospital alive. The author declares, however, that this does not indicate that one-third of all cases recover, because (1) the more severe cases are more commonly sent to hospitals, (2) mild cases are treated in dispensaries, and (3) many who are sent out alive die subsequently. The older the child, the better the prognosis. Any prognosis early in the disease is pure conjecture. The author has been able to follow up 17 cases sent out as cured. None of these have died, although the history extends over several years; 8 are completely cured; 5 have very minor troubles, which may be of no significance; 2 belong to the group "retarded development." There remain 2 who have developed hydrocephalus since leaving the hospital, but neither of these was really normal on leaving—one was still frequently vomiting, and in the other the limbs were still slightly spastic—so that one may conclude that once a child appears to

be completely cured of the disease the prognosis is very good; but when one turns to those who were sent out "better" or "improved," the outlook becomes distressing. Out of 7, only 3 survive. Of these, 1 has hydrocephalus, another is paralyzed, and the third shows "retarded development"; at 3½ she cannot walk alone; 4 died, 1 from scarlet fever (the exanthemata not infrequently carry off these patients during convalescence), and the other 3 from the disease itself or its sequelæ. Out of 13 cases sent out "in *statu quo*," 4 developed hydrocephalus while in hospital; 2 others died of "water on the brain" subsequently; 1 died of the disease itself, and 1 of measles; 3 are permanently disabled, and only 2 are cured.

Berliner klinische Wochenschrift, March 26, 1906.

The Upper Limit of Dullness in Accumulations of Fluid in the Pleural Cavity.—Krönig calls attention to a hitherto little-regarded observation made by Garland in 1878, to the effect that when considerable amounts of fluid are present in the pleural cavity, a triangular area of resonance, having its base upward, one side formed by the vertebral column, and the other by a line forming the beginning of Ellis's S-shaped curve, exists at the upper limit of fluid. This fact, he says, has been either denied or passed over without mention by most German authors, and he states that its existence was independently discovered by him before he had learned of Garland's observations. The triangle of resonance, according to his own observations, is, however, smaller than that recorded by Garland. The occurrence of aerated lung in this situation is to be expected when it is considered that the root of the lung occupies this situation, so that when the organ is compressed it must be pushed in this direction. The author believes that the demonstration of this paravertebral zone of resonance has importance not only from a theoretical standpoint, but also practically in making exploratory punctures for the demonstration of fluid.

Pulmonary Tuberculosis in School Children.—Roeder says that a true idea of the prevalence of this disease in children cannot be gained from hospital statistics, inasmuch as it has been found that a very large proportion of children so afflicted do not complain of illness until the disease has reached an advanced stage. Therefore it is necessary to make thorough physical examinations of all school children at regular intervals. Statistics of this sort recently obtained in Prussia show that tuberculosis is by far the most dangerous enemy of children during the ages from five to fifteen years. Roeder recommends for the purpose of combating this tendency, regular examinations of all school children, and instruction concerning the dangers of the disease. All children found affected should be sent to suitable convalescent homes or sanatoria, which must be provided in sufficient numbers. After an adequate period of treatment in these, the children should be transferred to settlements and schools situated in the country. Tuberculous children and those with a predisposition to the disease should be watched until the school course is finished, at which time all children should be examined and be provided with a certificate stating their condition of health.

Münchener medizinische Wochenschrift, March 27, 1906.

The Pharyngeal Reflex.—Baumann states that although the absence of this reflex is generally mentioned as an indication of hysteria, the subject has apparently not been studied very extensively in normal persons. He reports the result of a series of observations made on a large number of soldiers, of high school children, and of hospital patients, and comes to the following conclusions: A true retching movement is not essential to the pharyngeal reflex. A plainly visible contraction of the pharyngeal muscles is sufficient to be regarded as the reflex. Actual absence of the pharyngeal reflex is very rare, and when it is observed is usually only temporary. The reflex is exaggerated in young individuals oftener than in adults, and sometimes a psychical inhibition of the reflex may be noticed. Chronic pharyngeal catarrh ordinarily does not produce any exaggeration of the reflex, and in acute catarrhal conditions there is no regularity in its behavior. In hypertrophy of the tonsils without inflammatory swelling, a diminution of the reflex is ordinarily very rare.

Arteriosclerosis in Surgery.—Siegel says that although the administration of anesthetics to persons more than fifty or sixty years old and having arteriosclerosis, is usually a matter involving considerable anxiety, he has obtained the impression that such persons stand the anesthesia comparatively well, provided that the cardiac and renal activity is good, and that no pulmonary complications exist. The combination of emphysema and bronchitis, on the other hand, renders the outlook much less favorable. Very old persons, that is, those who have passed the eightieth year, and who require surgical intervention for some such cause as strangulated hernia, nearly always do well under chloroform anesthesia. Premature arteriosclerosis is often the cause of unpleasant surprises in the course of the narcosis, sudden collapse, followed by extremely feeble heart action, being not uncommon. Deep narcosis is less injurious to persons with arteriosclerosis than a more superficial anesthetization, which permits the heart to be influenced by persisting reflexes. Wounds usually heal satisfactorily in arteriosclerotics, although intestinal resections seem to form an exception to this general rule. The author suggests as causes of premature arteriosclerosis, abuse of alcohol, excessive cigarette smoking, and extreme depressions of temperature such as occur in those who take very cold baths in winter. Presenile gangrene is said to be especially common in Russian Poland and in Japan.

The Treatment of Joint Tuberculosis.—Gebele and Ebermayer present an outline of the methods of treatment for this condition in use in v. Angerer's clinic in Munich. The general position is taken that discrimination is necessary in selecting the plan of treatment to be followed, and that the extremely conservative methods that are popular at present are just as undesirable as the ultraoperative tendency which was dominant twenty-five years ago. The conservative treatment usually employed by the authors consists in fixation of the affected joint by means of a plaster-of-Paris or similar dressing. The injection of 10 per cent. iodoform and glycerin, in doses for adults of 5 to 10 c.c., repeated at intervals of from eight to fourteen days, has been found a useful adjuvant. Bier's method of treatment by hyperemia is also employed in selected cases, particularly in those accompanied by suppuration and sinuses, fixation ordinarily being used in conjunction with it. Due stress is laid on such accessories as good nourishment, ventilation of dwellings, and sojourn out of doors. The statistics of the clinic show that about a fourth of the patients operated on, in spite of arthrectomy and in some cases in spite of secondary amputation, were either not cured or died. The prospects of permanent cure after operation are much smaller for adults than for younger patients, and the authors believe that if operative measures are to be employed on grown patients, resection should not be used as a routine measure, but that if the case is advanced and is accompanied by demonstrable tuberculosis of the internal organs, primary amputation should be practised.

Deutsche medizinische Wochenschrift, March 29, 1906.

The Treatment of Pulmonary Tuberculosis by Means of Artificial Pneumothorax.—Schmidt speaks favorably of a plan of treating pulmonary tuberculosis, old unabsorbed pleural exudates, bronchiectasis with cavity formation, and emphysema by means of injections of gas or fluids into the pleural cavity. Gases such as pure oxygen and sterile air are used when it is desired to effect compression of the apex of the lung, and salt solution or oil when the base is to be influenced. The author has carried out the measure twenty times without encountering any complications. The procedure is effected by means of a special trocar in two parts. The first of these consists of a sharp needle of large caliber, provided with a heavy flange which prevents the point from penetrating more deeply than enough to pierce the intercostal muscles without puncturing the pleura. Through this instrument the cannula proper, which has a blunt end with lateral openings, is forced into the pleural cavity.

Experimental Observations on the Infectiousness of Syphilitic Blood.—Hoffmann reviews the recorded instances in which human beings were experimentally inoculated with syphilitic blood. Eighteen such observations have been described, with a positive result in seven of the number. This shows that the infectiousness of the blood is not very great, even in fresh, untreated syphilis, as the material for these experiments was in nearly every instance taken from early cases of the disease. Hoffmann's own experiments were made on four monkeys that were inoculated with virus from recently infected individuals. Two of the number developed chancres, while two did not. The *Spirochæta pallida* could be demonstrated in the lesions of the monkeys that were successfully inoculated.

Book Reviews.

Materia Medica for Nurses. By John E. Groff, Ph.G., Apothecary in the Rhode Island Hospital, Professor of Materia Medica, Botany, and Pharmacognosy in the Rhode Island College of Pharmacy. Third Edition, revised, with an appendix giving list of questions for self-examination. Based upon the eighth decennial revision of the U. S. Pharmacopeia. Philadelphia: P. Blakiston's Co., 1906.

The subject of Materia Medica as presented in this volume, while naturally condensed, is still sufficiently comprehensive to answer all the requirements of nurses. The book is written in a simple style, the arrangement is good, and the questions for examination are unusually sensible and practical.

Massage and the Original Swedish Movements, Their application to various diseases of the body. Lectures before the Training School for Nurses Connected with the Hospital of the University of Pennsylvania, German Hospital, Woman's Hospital, Philadelphia Lying-In Charity Hospital, the Philadelphia Polyclinic and College for Graduates in Medicine, and the Kensington Hospital for Women, of Philadelphia. By Kurre W. Ostrom, from the Royal University of Upsala, Sweden. Sixth Edition, revised and enlarged, with one hundred and fifteen illustrations. Philadelphia: P. Blakiston's Son & Co., 1905.

In this new edition the subject-matter of the book has undergone careful revision; the practical instructions for giving massage have been enlarged; and there are new sections dealing with headache, the prostate gland, colds, affections of the bladder, varicose veins, and hernia. The book is written by one who has enjoyed considerable practical experience in massage and Swedish movements, and it will be of service to physicians, nurses, and professional masseurs and masseuses. There are numerous illustrations, but they are not of a high order of artistic merit.

A Manual of Materia Medica and Pharmacology, comprising all organic and inorganic drugs which are or have been official in the U. S. Pharmacopeia together with important allied species and useful synthetics. By David M. R. Culbreth, Ph.G., M.D., Professor of Botany, Materia Medica, and Pharmacognosy in the University of Maryland Dental, Medical, and Pharmaceutical Schools. Fourth Edition, enlarged and thoroughly revised. Philadelphia and New York: Lea Brothers & Co., 1906.

This, the fourth edition of Culbreth's work, is brought up to date and made to conform to the U. S. Pharmacopeia. It opens with a general discussion of materia medica and the physiological action of drugs, including the form in use, avenues through which they enter the circulation, the means by which they are carried through the human system, and the channels by or through which they are eliminated, the conditions which exist to modify their action, and the doses. This is followed by remarks as to classification, the chemical, morphological, botanical, and therapeutic action and characteristics.

The larger part is taken up with a description of organic drugs from vegetable and animal sources, inorganic drugs from the mineral world, carbon compounds, and a partial list of the synthetics, including those incorporated in the lately issued Pharmacopeia. Finally a chapter is given to the study of the microscope as it applies to materia medica. The chapter on non-pharmacopeial organic carbon compounds (synthetic remedies) is useful, as it gives information concerning the new remedies together with doses. After all, these products have an established place in the physician's armamentarium, and it is wise to give such information concerning them as will help to their proper uses. The book will be found useful to students in pharmacy of medicine, both as a textbook and for reference.

International Clinics. A Quarterly Review of Illustrated Clinical Lectures. Edited by A. O. J. Kelly, A.M., M.D., with the collaboration of Wm. Osler, M.D. (Oxford), John H. Musser, M.D. (Philadelphia), and others. Vol. IV. Fifteenth Series. Philadelphia and London: J. B. Lippincott Company, 1906.

A beautiful colored plate of Psoriasis attracts attention at once on opening this volume to Dr. Gottheil's excellent article on the subject. Another striking contribution is that of Warthin of Ann Arbor, on an experimental study of the effects of *x*-rays upon the blood-forming organs, with special reference to the treatment of leukemia. Including the illustrations, it takes up thirty-four pages. Ectopic pregnancy has been interestingly and artistically depicted by Ashby of Baltimore, followed by sixty cases of extra-uterine pregnancy by Newell of Boston. The *x*-ray in joint tuberculosis by Freiberg of Cincinnati is an interesting study of the clinical course of the disease, and these are only a few of the articles of worth.

A Systematic Course of Qualitative Chemical Analysis of Inorganic and Organic Substances. With explanatory notes. By Henry W. Schimpf, Ph.G., M.D., Professor of Analytical Chemistry in the Brooklyn College of Pharmacy. New York: John Wiley & Sons, 1906.

This manual differs from some of its class by presenting a series of explanatory notes which cover essential facts in chemistry that aid the students in understanding the analytic processes in which he is engaged. The work is written by a practical teacher, and every effort has been made to simplify his subject and to render its essentials more easily grasped by the beginner. The most important portion of the book from the viewpoint of medicine is the chart devoted to the detection of the most common organic pharmaceuticals, such as acetphennetidin, aloin, quinine, etc., etc. Professor Bartley's scheme for a systematic examination and identification of unknown organic substances commonly used in pharmacy, medicine, and the arts is also included in the book. A rather scanty scheme for the detection of poisons, and an entirely inadequate scheme for uranalysis (especially deficient as to the microscopical examination) complete the volume.

A Textbook of Pharmacology and Therapeutics, or the Action of Drugs in Health and Disease. By Arthur R. Cushing, M.A., M.D., Aberdeen, Professor of Pharmacology in the University College, London, England; formerly Professor of Materia Medica and Therapeutics in the University of Michigan. Fourth Edition, thoroughly revised. Illustrated with fifty-two engravings. Philadelphia and New York: Lea Brothers & Co., 1906.

The many admirers of Dr. Cushing's excellent work will be pleased to see the appearance of this revision which has brought the text into conformity with the New United States Pharmacopeia. The chief changes noted are those entailed by this modification, though numerous sections, notably those on chloroform and wood alcohol, have been brought into harmony with the results of recent investigation and experience. The book is one of the most valuable of its class, and fully deserves the popularity it seems to have attained.

A Manual of Bacteriology. By Herbert U. Williams, M.D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. Revised by B. Meade Bolton, M.D., Expert, Bureau of Animal Industry, Washington, D.C. With 108 Illustrations. Fourth Edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1905.

The previous editions of this work have been favorably noticed in these columns, and the changes apparent in the present revision are sufficiently numerous to keep it abreast of the progress that has been made in bacteriology. The chapter on immunity especially has been subjected to considerable amplification and does justice to the hypotheses of Metchnikoff, Bordet, and Arrhenius, as well as to the rather more popular one of Ehrlich.

The Changes Produced by Inflammation in the Conjunctiva. (Hunterian Lectures, R.C.S., 1905.) By M. S. Mayou, F.R.C.S., Jacksonian Prizeman and Hunterian Professor, Royal College of Surgeons, England; Ophthalmic Surgeon to the Hospital for Paralysis and Epilepsy, Maida Vale; Chief Clinical Assistant to Royal London Ophthalmic and London Hospitals. "Fiat Lux." New York: William Wood & Co., 1906.

This book, which is one of 179 pages, is devoted to a description of observations made in original research work. It is well illustrated, having four colored plates and one black and white plate and forty-four figures in the text. The first lecture describes briefly the development of the eyelids, with special reference to the condition of the conjunctiva before the separation of the margins of the lids, the studies being extended to animals other than man. The cytology of the normal conjunctiva and a description of the changes in the surface cells that occur in xerosis conjunctivæ are given. The second lecture takes up the consideration of changes that take place in the conjunctiva (1) as a result of wounds, (2) in the development of lymphoid tissue, (3) due to conjunctivitis produced by micro-organisms. In the third lecture the author takes up the consideration of trachoma, discussing it from the viewpoint of the histologist, based on data obtained by careful laboratory work with material skilfully selected and studied. An attempt is made to differentiate between follicular conjunctivitis and trachoma. The arrangement of sanatoria and the treatment of trachoma are entered into. Phlyctenular and vernal catarrh are also fully discussed.

The book marks a decided advance in our knowledge of the conditions discussed. It represents a great amount of labor and careful research. It is well written and is deserving of the careful study of all ophthalmologists.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held March 15, 1906.

DR. CHARLES L. DANA IN THE CHAIR.

A Study of the Spirochæta Pallida, with Demonstrations.— Mr. L. B. GOLDHORN gave a lantern-slide demonstration of his personal work done on cases of primary, secondary, and congenital syphilis. He said he had had an opportunity to examine over sixty cases of primary and secondary lesions, and in all, with the exception of eight or nine, he had succeeded in finding the organism. This organism was stained by him in a peculiar manner, which he had described in a paper before the Pathological Society three months ago. The method used enabled him to discover the organism almost constantly. He drew especial attention to the fact that, in order to succeed, one must remove any exudate present; it would be impossible to find the spirochete when there were pus corpuscles on the smear. He advised the use of the curette, applied at the edge of the lesion rather than at the center. He emphasized the importance of examining more than one lesion. He had as yet no conclusions to offer regarding the diagnostic value of the spirochete. He related one case of interest in which there were simultaneous initial lesions occurring on the tongue and penis in which he failed to find *Spirochæta pallida*. In seven weeks no secondary lesions had appeared.

Dr. SIMON FLEXNER referred to the paper he had read before the Academy three or four months ago (see MEDICAL RECORD, November 11, 1905, page 798). Cultures and inoculations had not been successfully carried out at the time of writing his paper; up to the present moment certain requirements had not been fulfilled. But the demonstration of Mr. Goldhorn made such a chain of evidence that it must be believed. At the same time he believed we should go slow in the interpretation of the findings on the smear at present, because the methods of staining used to-day were imperfect at best. He thought the clinical demonstration of the *Spirochæta pallida* in the office was practical.

Dr. HARLOW BROOKS called attention to the difficulties attending present and older methods of staining, and said that Mr. Goldhorn had presented a very much easier method. The constancy with which the spirochete appeared in fresh lesions was quite striking.

Dr. LAPOWSKI and Dr. NORRIS discussed the demonstration.

The Condition of the Air of the Rapid Transit Subway.—Dr. GEORGE A. SOPER read this paper (see page 609).

Dr. S. ADOLPHUS KNOPF said he was glad to hear Dr. Soper call attention to the dangers of infection attending sneezing and dry coughing, and believed that if signs were placed telling of the dangers of sneezing and coughing in one's face, the people would take it to heart and be more careful. The results of prohibitory signs had not been entirely successful, and he wondered if it would not be better to provide a number of spittoons and over each place the sign, "Spit here." Dr. Knopf was alarmed regarding the health of the employees, who were obliged to work in the dust-laden atmosphere of the subway 10 and 12 hours a day. The consequent irritation of the respiratory tract invited such diseases as tuberculosis and pneumonia, and he ventured a suggestion that, since the subway and elevated roads were run by the same company, the employees of each road alternate, at least until the time came when the danger of this dust was done away with. By so doing he believed the danger of the employees becoming diseased would be reduced by at least 50 per cent. The odors in the subway were produced not only by the oil and the material in the roadbed, but by the crowds who traveled this odor could not be designated; it was an odor like that of prisons, among the poor, etc., an odor that was quite characteristic of crowded humanity. He hoped the subway authorities would take to heart the suggestions offered in the paper of Dr. Soper, and especially the health of the employees.

Dr. BASSLER asked Dr. Soper whether there was any difference in the heat point between stations, or in the amount of CO_2.

Dr. Soper said he keenly felt the limitations of his work, and hoped that it would only be a preliminary report upon something which would be better in every way. We were on the eve of beginning an era of subway building, and every effort should be made so that the subway travel should not be injurious to health. The health of the employee should also be considered. It was the purpose of the Commission to have investigations made regarding the health of the employees in order to determine whether any injury was being done to their physical condition or not. There seemed to be ample air in the subway. There were 35,000,000 cubic feet, on 21 miles of roads. The air was examined between the stations both for temperatures and CO_2, as well as for bacteria, but no material differences were found, a rather surprising discovery and one which afforded much relief. To let more air in and out of the subway the lid should be lifted. It was noted that the air above Fiftieth street was far better than the air below, because the proportion between the area of openings and the cubic contents was much lower below than above that point.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Regular Meeting Held March 20, 1906.

DR. WILLIAM F. CAMPBELL IN THE CHAIR.

Custom and Fashion in Surgery.—Dr. JOHN CHALMERS DA COSTA of Philadelphia read this paper. He said that the tendencies of modern surgery showed the effect not so much of custom as of fashion. We passed into error because we did not stop to think. There were fashions in surgery as in neckties and bonnets. Fashions in millinery were obtained in Paris; fashions in surgery were imported from Germany. One of the customs of surgery that had been carried to an extreme and blindly followed was that of exploratory incisions. In the time of Charles the Second, Butler in his Hudibras referred to the custom of "being dissected to see what part is disaffected." At present the exploratory operation had developed extraordinary refinements. Not alone did surgeons cut into the peritoneal cavity, but they had lately been advised to cut down to the peritoneum, and palpate it from without. Likewise an incision as far as the parietal pleura had been advised. As the result of an exploratory operation the surgeon might decide on a radical or a palliative operation, or he might find that a further operation was inadvisable or impossible. He who attempted an exploratory operation must have great experience. He should have a mental picture of what he might expect to find; such a sharply-defined image could be acquired only by experience. The finger felt and the eye saw what the brain made the finger feel or the eye see. One man might feel and see what another man could not feel or see. The normal thickening of the pyloric sphincter might be mistaken for a stricture. An inflammatory thickening of the head of the pancreas might be mistaken for a stone in the common duct, etc. One should protest against the exploratory operation when it was not required. Not only should it not be performed without experience, but it should not be resorted to until all the clinical means at one's disposal had been exhausted. But a calamity might require immediate operation. Every abdominal and brain operation was to a certain extent exploratory. In some cases the exploratory incision

was a benefit itself, in other cases it showed what further surgical procedures should be resorted to. The indiscriminate use of the exploratory operation had frequently led to this habit of thought: "Why strain the mind to make a diagnosis when by making a simple incision the exact condition is plainly revealed?" It is remarkable that in the evolutions of modern surgery a decided advance had been made in surgical technique, and but little progress had been made in surgical diagnosis. It was high time to protest against the attitude which only too frequently made the surgeon but an ignorant knifeman like the barber of former days. The surgeon ought to become the best of diagnosticians. He who never thought of making a diagnosis without an exploratory operation would many a time make a needless exploration. The abdomen was frequently opened with as little concern as a drawer might be pulled from the bureau in order to examine its contents. To every patient the exploratory operation was of considerable moment. No incision ought to be merely exploratory; it should be ultimately diagnostic.

One of the prevailing fashions of surgery was the strict cultivation of aseptic and antiseptic methods. The history of antiseptic surgery revealed the same habits of thought and practice as other branches of human philosophy and art. Creeds passed away not because of the arguments that were hurled against them, but because men's minds were predisposed against them. Argument was usually accepted only as a justification for the abolishment of a certain system of thought and policy. The annals of antiseptic surgery illustrated this truth. Semmelweis in 1847 suggested that puerperal fever was infectious. In 1863 Jules Lemaire advocated the use of carbolic acid in the treatment of wounds. The teachings of Lister did not at first fall upon attentive ears. Even as late as 1882 only four surgeons in Philadelphia followed the teachings of Lister. The 19th century was the age of turmoil, of revolution in methods, ideas, and ideals. Medical men accepted antiseptic surgery not because they believed in it, but because they were predisposed in favor of it. In fact the refinements of aseptic surgery have been carried too far. Desault said one hundred years ago that the simplicity of an operation was the test of its perfection. This was true of the methods of hand sterilization. The operating room had developed into a palatial theater, of which the charity patient reaped the benefit. The rich rarely shared the luxury. To be sure certain things were essential in the operating room, but some were useless, some mere accessories, and some were not desirable. Complicated methods resulted from working a theory to an extreme. The main danger to be avoided in an operating room was dust. A wooden table covered with blankets was wellnigh as good as a table of glass or metal. The facial mask was unnecessary, as were the "fisherman's boots." Fallacies regarding the various antiseptics had grown apace with these requirements. It was not generally known that iodoform was not germicidal when dusted on free surfaces, but was germicidal in an inclosed space like a tuberculous cavity. Heilé had explained the antiseptic efficiency of iodoform on the theory that the tissue juices decomposed the drugs. Thus iodoform was a good clinical but a poor laboratory germicide. On the other hand, corrosive sublimate, which was a good laboratory germicide, was but a poor one clinically. It was too often forgotten that the test tube had no vital resistance. The simpler methods of hand disinfection were much more satisfactory than the complicated ones. The basis should be thorough mechanical cleansing. Surgeons frequently forgot to use the brush crosswise so as to get into the transverse crevices of the skin. The water should be very hot so as to produce a profuse flow of sweat. There was no advantage in the use of germicidal soaps. Sand soap or marble soap was not advised. Prolonged scrubbing loosened the epithelium and made it liable to fall into the wound. The scrubbing should last five minutes and should be followed by the alcohol sublimate method of disinfection. Gloves were to be reserved for infected cases; it was also safer to wear them when invading the peritoneum or the large joints.

Another one of the fashions of modern surgery was the intravenous injection of salt solution. There were different ideas as to the proper temperature at which the saline injection should be given. It was ordinarily given at 103°, but Dawbarn gave it as high at 118°, It was hardly realized that the saline injection was not only sometimes harmful, but was also frequently dangerous. The intravenous saline injection had been frequently resorted to in infectious diseases so as to wash out the toxins and to produce an increased diuresis. But the latter was the exception rather than the rule. Often the injection of a large amount of fluid into the blood might actually suppress diuresis; it might lead to an increase in a pleural effusion; it might cause a retention of sodium chloride in the tissues. The injection of salt solution had been hailed as a powerful curative measure in shock. This condition might be due to exhaustion of the vasomotor center, or to collapse from injury of the vasomotor center, or heart failure following hemorrhage. Crile had shown that shock was only temporarily relieved by saline injection. But in shock due to hemorrhage the method was of value. On the other hand it had been productive of harm in urinary suppression of renal or cardiac origin, and had even produced fatalities in edema of the lungs and dilatation of the heart.

Another one of the customs of modern surgery that required thorough overhauling was that of the respective use of heat and cold in inflammatory conditions. It was overlooked that inflammation was a process and not a state. Cold was of value in the proper stages of inflammation, but it should not be applied so as to chill the tissues. The indiscriminate use of the ice-bag might produce dangerous stasis and necrosis in the parts underlying it. Cold should be applied only in the earliest stages of inflammation, during the condition of pure hyperemia which lasted for but a few hours. In the latter stages the ice-bag might relieve the pain and lessen the muscular rigidity, but it masked the symptoms. Still worse, it inhibited the emigration of leucocytes. It thus counteracted nature's effort to limit the area of inflammation with a barrier of leucocytes. It thus might favor the spread of the inflammation. If the cold was too intense, if its application was too prolonged or too late, when stasis, exudation, and swelling had resulted, then cold did serious harm. It lessened nutritive activity of the cells, it lessened phagocytosis, it lessened vitality. In most cases of appendicitis the application of the ice-bag was harmful, for three reasons. (1) The patients were never seen so early as to warrant the use of cold; (2) the ice-bag masked the symptoms; (3) the cold prevented the migration of the leucocytes. Not only was the ice-bag responsible for the delaying of the operation, but it was also responsible for the gangrene that so frequently occurred. When stasis was confined to the focus of the inflammation, cold should be used continuously and not intermittently, owing to the reaction that would occur in the intervals between each application. Cold might be comfortable and yet do harm. It should

never be used for a period longer than twenty-four hours. As regarded heat, it might be continuous or intermittent, dry or moist. A high degree of heat had the same action as cold. Heat does harm in a surface inflammation, or in erysipelas. In subcutaneous or deep inflammations, heat in whatever form did good. It produced a moderate degree of venous dilatation and drained the inflamed area. This venous drainage established the circulation and the swelling abated. Moreover, phagocytosis was increased, and pain, rigidity, and tenderness were diminished.

Dr. Frederick Holme Wiggin of New York opened the discussion. He said that Dr. Da Costa's paper was an exhaustive one. A few points alluded to required further emphasis. One of these was that one should never perform an exploratory operation unless there was a good reason for it. On the other hand a patient might be dying on account of the delay occasioned by differences of opinion as to the nature of the surgical diagnosis. The necessity of experience and skill in him who undertook an exploratory operation was also worth further emphasis. The speaker alluded to a case in which two physicians made an abdominal section and then called him in to complete the operation, after several hours, as they did not know what to do. As regarded mechanical cleansing of the hands he found that gauze was better than the brush, not causing the peeling of the epithelium. Following thorough cleansing with gauze and tincture of green soap, the hands were washed in 65 per cent. alcohol, and then placed in a strong alcoholic solution of bichloride (1-300) for a few seconds. In recent years, instead of rubber gloves he had used a thin coating of celloidin for the hands. This was flexible and could be removed with equal parts of ether and alcohol, but this method is adapted only for hospital work. Celloidin might be used in a similar 10 per cent. solution for sealing the abdominal wound. The speaker agreed with the author of the paper in holding that too much reliance had been placed on the use of the saline injection. As regarded the prevention of shock, he had found that the moderate use of ergot for a week or ten days previous to the operation tended to reduce the possibility of shock and also tended to calm the nervous system. It put the patient in such a condition that frequently the pulse rate would not exceed 85 at any time during the operation. Ergot might also be administered shortly before, during, and after the operation. It might thus obviate the use of morphine. The speaker confined the employment of the saline injection to cases of hemorrhage. He had found that an enema of one pint of the saline solution every four hours was frequently sufficient. He agreed with the author as regarded the mutual indications for the use of heat and cold in the treatment of inflammatory conditions.

Dr. J. Riddle Goffe expressed himself in sympathy with a more careful attitude regarding exploratory operations. Reckless operations should be avoided. But the exploratory operation had its place. By its means alone was Emmet able to place his hand in the pelvis and show that what had been regarded as a pelvic cellulitis was frequently really a salpingo-ovarian abscess. As regarded shock, he did not believe that the last word had been said. As a sheet-anchor in this condition was morphine, promptly and freely administered. His experience in the use of saline solution had been so satisfactory that he would not give up this therapeutic procedure in the treatment of various conditions confronting the surgeon until something better presented itself.

Dr. John Welsh Croskey of Philadelphia closed the discussion.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, March 12, 1906.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Report of the Committee on the Death of Dr. Emmet C. Dent.—By Dr. Robert Coleman Kemp, Chairman. (Read by the Secretary.)

Report of the Committee on the Death of Dr. William E. Swan.—By Dr. Samuel Lloyd, Chairman.

Symposium on the Present Status of Radiology in Diagnosis and Treatment.—Dr. A. D. Rockwell opened the discussion in a paper on *x*-ray therapy. (See page 617.)

Dr. John H. Musser of Philadelphia discussed the value of the *x*-rays as a diagnostic aid in cardiovascular and gastrointestinal conditions. While in many obscure cases, especially those relating to the abdomen, the evidence furnished by the rays was simply confirmatory, it was to be expected that with improved technique and enlarged experience this method of diagnosis would prove of much greater value in the future. In speaking of the use of the *x*-ray in cardiovascular conditions, Dr. Musser said that the presence of an aneurysm in the thoracic cavity had been positively demonstrated by this means over and over again, and in that connection he called attention to the possibility of multiple aneurysms being present. By means of the *x*-ray the shape, size, and position of the heart could readily be demonstrated, and for that purpose the method was particularly valuable in dealing with fat people and with women. The presence of mediastinal growths and enlarged glands could also be shown by the rays. In dealing with pulmonary conditions, the rays enabled us to distinguish between consolidation and effusion, and to localize pulmonary abscesses.

Drs. Henry Pancoast and W. S. Newcomet of Philadelphia showed a number of radioscopic pictures in illustration of the remarks made by Dr. Musser regarding the value of the *x*-rays in the recognition of certain cardiovascular and gastrointestinal conditions. In those relating to the esophagus, stomach, and intestines, Dr. Pancoast explained that the radiographs had been taken immediately after the patients had swallowed an emulsion of bismuth, by which means a very distinct outline of the organs of the gastrointestinal tract could be obtained by the proper time and degree of exposure.

Dr. William B. Coley read a paper on the value of the *x*-ray in cancer, in which he offered the following conclusions: (1) That the *x*-rays had an undoubted and oftentimes remarkable influence upon cutaneous carcinoma or superficial epithelioma, resulting frequently in the entire disappearance of the lesion, and sometimes in a permanent cure. There was, however, a strong tendency to recurrence, and it was still an open question whether it was not better to excise even superficial growths when possible, reserving the use of the *x*-rays for cases beyond operation. (2) In deep-seated cancer, both carcinoma and sarcoma, the influence of the *x*-rays was in most cases slight and temporary. The few cases in which there had been an apparent disappearance of the tumor had, in almost every instance, been quickly followed by either local or metastatic recurrence. For that reason the *x*-rays should never be used in operable deep-seated cancer. (3) The temporary improvement observed in a certain number of cases, as evidenced by decrease in size or cessation of growth, together with considerable diminution in pain, justified the use of the *x*-rays in cases of inoperable, deep-seated cancer as a palliative measure. (4) The use of the *x*-rays as a preoperative measure in operable cancer was strongly to be condemned. (*a*) because the disease might, and often did, extend locally, or, more especially, by metastases, during the period of preoperative treatment; (*b*) aside from such real dangers, the speaker said he could not see any advantages to be gained

by such a course of treatment. If the tumor did not decrease in size, there was certainly nothing gained; if it did decrease in size, and the neighboring glands became smaller, there was the danger that the operation would be less radical than if done at first, and that infective tissue might be left behind as a source of future recurrence. (5) The value of the *x*-rays as a prophylactic measure after operation for primary malignant tumors, so strongly advised by most *x*-ray workers, at present rested entirely upon theoretical grounds. There were absolutely no data to prove such value, while there were many observations that would tend to disprove the same, or to reduce it to a minimum. It would require many more observations and a much longer period of time before a positive opinion could be expressed. In advising such treatment after operation, the patient should be told that it was entirely experimental, and, furthermore, should not be kept ignorant of the fact that in a number of cases the prolonged exposure to the *x*-rays had caused cancer in a previously healthy individual.

Dr. Carl Beck, in discussing the *x*-ray in surgical diagnosis, emphasized particularly the value of the rays in the recognition and treatment of fractures. Whereas formerly text-books were written on this subject, and the nature and treatment of various fractures were fruitful sources of controversy, this entire field of surgery had practically been revolutionized by the introduction of the *x*-rays, and could now be covered in a few pages. The *x*-rays showed what the condition was, and, knowing that, the treatment naturally suggested itself. In addition to fractures and their operative correction, Dr. Beck referred to the value of the rays in the recognition of foreign bodies, and in differentiating between osteomyelitis, necrosis (the extraction of sequestra under the guidance of the Roentgen rays), acute inflammatory atrophy in osseous tissues, tuberculosis of the bones and joints, osteomalacia, arthritis, syphilis, neoplasms (especially osteosarcoma), and the special features of osseous cysts, acromegaly, and exostoses. Sclerotic changes in the arteries and veins were also touched upon, as well as concretions of the biliary and urinary tracts.

The Value of Radium in Surgery.—Dr. Robert Abbe said that the great difficulty in obtaining radium of sufficient strength was due to the fact that its source of supply was very limited. The radium seemed to exert a more intense action on morbid than on healthy tissues, and of the former, carcinoma and rodent ulcers of the face were especially amenable to it. It possessed the same penetrative power as the *x*-ray, and apparently produced a retrograde action of the morbid cells, which were, perhaps, in the nature of slumbering cells or "rests," and which had grown up into morbid growths. In some cases in which the Roentgen ray had failed, radium had succeeded very strikingly, showing that we are dealing with somewhat different types of rays. To illustrate the value of radium in surgery, Dr. Abbe showed a number of colored models of various pathological conditions before and after successful treatment. Among these were cases of warts on the face and hands, epitheliomata of the nose and lip, rodent ulcer of the face, old, intractable cases of lupus, a case of alveolar sarcoma of the eyelid, and one of giant-celled sarcoma of the lower jaw. Also cases of mammary carcinoma and cancer of the tongue (still under observation), and in goiter of the exophthalmic type.

Dr. Henry G. Piffard said he was not an enthusiastic advocate of the *x*-ray as a therapeutic measure. He had seen so much harm done by it, and had seen and heard of so many cases that could have been treated to better advantage in other ways, that he had not resorted to it to the extent that many had done, nor did he value it as much as he did other and older remedies. Many men used the *x*-ray who had not a proper knowledge of the subject. A man who bought an *x*-ray apparatus and turned on the switch did not thereby make himself a radiotherapeutist. The treatment could not be administered properly without some knowledge of the rays themselves. The majority of cases of skin diseases and superficial affections could be cured more easily and more cheaply by methods that were in vogue before the introduction of the *x*-ray. There were two conditions of the skin, however, in which the application of the ray was apparently superior to other methods, namely, mycosis fungoides and ringworm of the scalp.

Dr. Edward B. Bronson said he would limit his remarks to the good effect of the *x*-rays in some of the simpler forms of disease of the skin. Such simple affections as acne, rosacea, rebellious callosities of the palms and soles, inveterate squamous or psoriatic forms of eczema, and many other chronic cutaneous troubles of a superficial character, when they did not readily yield to the commoner methods of treatment, might often be made to succumb to Roentgen radiation with a facility that was surprising, nor need there be any ill after-effects worth considering. Thereby not only might the skin be restored to its normal appearance in a comparatively short period, but also in many cases would the disposition to recurrences be markedly diminished. The tendency of the action of the rays was to produce involution or atrophy. Newly-formed cells were the first to undergo destruction, and the problem was to avail ourselves of this involutional tendency just to the extent of counteracting the disease process, without overstepping the margin of safety. It often happened that the best results followed a slight local inflammatory reaction. This was especially true of acne and rosacea. The reaction should be slight, but definite; just a moderate degree of erythema. The sooner this was effected, the better, and the less prolonged the treatment. Perhaps, in the treatment of psoriasis with the *x*-rays, a quicker and more permanent result would be obtained were the radiations pushed to the reaction point. This, Dr. Bronson said, he had never ventured to do, as the lesions disappeared rapidly enough under the combined use of the rays and chrysarobin. But it was always the rayed patches, even if the worst, that showed the most rapid involution; much more rapid than those treated only with chrysarobin. He was also inclined to believe that the rayed areas were less disposed to relapse. The speaker said that his experience with the rays in hirsuties had not been unfavorable, and for some bad cases it answered better than electrolysis. While there were few, if any, diseases in which the use of the *x*-rays was to be commended as an exclusive method of treatment, as an adjuvant to other methods, or, rather, as an extra force introduced for the purpose of overcoming an inertia otherwise intractable, it had a distinct and extraordinary value, but a value unfortunately not devoid of risks.

Dr. Charles W. Allen said that a few years ago the subject of *x*-ray therapeutics was spoken of as being in its infancy. Personally, he thought it was just as much in its infancy now as it was then, and that we were just beginning to realize what the *x*-ray had done for medicine and for humanity. He objected to the free tendency of the surgeon to suggest excision as the only alternative in the treatment of skin cancers, and claimed that there was a virtue in caustic paste which was not second to that of the knife and that there were strong reasons often for preferring it. Apart from the inherent value of the *x*-ray, it had done good in giving the patients a certain degree of confidence that something could be done for them, and thus permit of other efficacious measures. If the lesion was such that it did not respond to the *x*-ray, then we could resort to caustic paste, or, if necessary, the knife, and in many instances the older methods give more prompt if not better results.

Dr. J. Edward Stubbert spoke of the value of the *x*-ray as a diagnostic aid in the recognition of tuberculosis, empyema, pleurisy, and miliary tuberculosis. In the latter he considered it of great value. Even in cases of incipient pulmonary tuberculosis he had found it a valuable adjunct to other methods of diagnosis, and in a few instances he had been able to make the diagnosis by the *x*-ray findings alone, before any physical signs could be detected. As a therapeu-

tic agent, the ray was of value in promoting absorption of slight consolidations, and in reducing the various cocci in mixed infection of more advanced cases. Its greatest value, however, was in diagnosis.

Dr. Sinclair Tousey, in discussing the subject of the application of the *x*-ray in surgery, said that recent improvements in technique had made it possible to take pictures through the entire thickness of the head with such a degree of clearness of detail as to be of positive assistance in the diagnosis of disease of the antrum and other pneumatic sinuses. To illustrate this fact, the speaker exhibited two radiographs, one revealing the presence of pus in the ethmoidal cells, and the other in the antrum. Dr. Tousey said that a knowledge of the amount of *x*-ray which it took to produce certain physiological effects was of paramount importance. It was necessary to know this in order to enable one to apply the ray safely both for examination purposes and in order to produce the desired curative effect in cases of cancer and other conditions in which the applitions were deemed advisable. His own method, which he had used for a year, was applicable to each and every exposure; it consisted of an intensimetric scale by which the intensity of the rays could be estimated with a reasonable degree of accuracy. The scale was based upon the measurement of the distance to which the *x*-ray would carry and still produce visible fluorescence in a fluoroscope which was held to the examiner's eye.

Dr. Lewis Gregory Cole said that some of the pictures of fractures shown by Dr. Beck might prove misleading if only a single radiograph of the lesion were taken. A picture which showed the fragments in perfect apposition in one direction might disclose a marked displacement of the fragment with overriding of an inch or more in another direction. Dr. Cole said that two distinct kinds of rays were emitted by the *x*-ray tube in about equal amounts. These he described as direct and indirect rays; they were distinctly different radiographically, and why not therapeutically? When once their true significance was understood, the efficacy and safety of *x*-ray therapeutics would undoubtedly be much enhanced.

Dr. J. Herman Branth said that to rely for diagnostic purposes simply on a fluoroscopic examination would often lead to mistakes. A skiagraph was by far more reliable, but by no means infallible. To illustrate this, Dr. Branth showed a number of skiagraphs of bones, and although the latter were in separate pieces, the lines of separation in the pictures were concealed and invisible. The skiagraphs emphasized the importance of the fact that the plane of the fracture should be placed vertical to the plane of the photographic plate in order to bring out the fracture line. As a therapeutic measure, the Roentgen rays furnished perhaps even more variable results than in skiagraphy, for there entered as factors the idiosyncrasy of the patient, the constitutional condition, the progress and stage of the ailment, etc. If it was too far advanced, even the best remedy would avail nothing, and it would be an error to condemn the *x*-ray on such experience. Another question that came up was, Should the *x*-ray be used exclusively, or should it be combined with medical treatment, so as to bring the body into the best possible defensive condition, in order to facilitate repair and restore the vital processes to a proper balance?

Temperamental Dietetics.—According to a statement ascribed to Prof. Boyd Laynard by the *St James's Gazette*, eels must not be eaten by brain workers, chilly persons should cultivate a taste for sardines, while irritable people are warned away from ginger, and the melancholy man must not touch bacon. Whitebait is inadvisable for persons who are of an amorous nature, asparagus is forbidden to those who suffer from excitement, and languid persons are told to be careful when they indulge in peas, potatoes, arrowroot, and macaroni. Duck is described as unsuitable for the bashful, the irate, the pale, the drowsy, and the inebriate.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.

Eighteenth Semi-Annual Meeting, Held at St. Joseph, Mo., March 22 and 23, 1906.

Dr. John E. Summers of Omaha, President.

(*Concluded from page 604.*)

Club-Foot, with Special Reference to Post-Operative Treatment.—Dr. M. M. Edmonson of Kansas City, Mo., said that by beginning treatment early the foot could always be corrected by force alone. The soft tissues were easily stretched, and the bones that were malformed, especially the astragalus, were soft and cartilaginous, so that they could readily be moulded to conform to a normal position. At this stage it would require very little force to maintain this position, and it could be accomplished without causing pain. In its new position, the foot would develop normally with the rest of the body. The contracted tendons and soft tissues having been stretched, the elongated tendons would become contracted. In maintaining the corrected position at this age, a fixed dressing was probably used more than any other, especially plaster-of-Paris, but in this the ankle-joint was immobilized and all the advantages of muscular exercise were lost. It was often difficult to apply the dressing so that the position was as good as that gained by the hand. The Barwell dressing had all the advantages and none of the disadvantages of the plaster-of-Paris or any fixed dressing. It was simply and easily applied. No case should be cut that could be corrected by force. Following any method of correction, some mechanical support was necessary; as the primary cause still existed, some aid must be given in maintaining this muscular balance until nature alone was sufficient, and this could be reached only when the foot could be everted and flexed as easily as it could be inverted and extended. Feeling the need of a simple, yet effective retaining force in those cases, about four years ago the author devised a brace which he had found more nearly met all requirements. The shoe used in connection with the brace was the usual one made for the normal foot. It, however, should be heavy and made of the best material. This brace and its method of application were described, and cases in point cited.

The Indirect Effects of Valvular Lesions.—Dr. W. F. Milroy of Omaha said that all cell life and activity depended upon a proper blood supply. For this the heart was responsible. Therefore, a defective circulation might manifest itself in any part of the body. Valvular defects were met by compensatory hypertrophy, and yet this never restored a perfectly normal circulation. The author called particular attention to the wide range of symptoms not obviously connected with the heart. These were associated with the gastro-intestinal, respiratory, or the nervous system, or were more general, as loss of weight, power of concentration, or endurance. The date of origin of the symptoms was uncertain, their duration often many years. It was particularly insisted that in the vast majority of cases the development of symptoms was slow and insidious. Endocarditis, which caused the lesion, was secondary to many general infections. A history of rheumatism suggested an examination of the heart for valvular disease, but in the writer's opinion too much importance was given this infection in the etiology. Valvular disease was of far more frequent occurrence than was generally supposed. Clinical teachers and textbook writers were at fault in not emphasizing sufficiently their indirect effects. Gross errors in diagnosis were of very common occurrence. They suggested the necessity

for more attentive study of the art of physical diagnosis by the practitioner and the wisdom of an invariable rule in making such examinations a part of every diagnosis.

Rupture of the Male Urethra.—Dr. B. A. McDERMOTT of Omaha discussed some of the principles in the treatment of this condition. After speaking of the clinical pathology, the symptoms in penile rupture, and the symptoms of rupture of the membranous and bulbous portion of the urethra, both local and constitutional, he pointed out the indications for surgical interference, based upon the following reasons: (1) In cases of rupture of the urethra, immediate perineal or suprapubic section, with suture of the ruptured ends of the urethra, should be practised. (2) By this procedure not only were the sufferings of the patient lessened, as well as the danger of urinary infiltration and abscess, but in a large number of cases the formation of a later stricture might be prevented. (3) In early operation the search for the posterior end of the urethra was much easier than it was later, as the tissues were not so infiltrated and the posterior end was not so retracted. The hemorrhage from the branches of the arteries of the bulb served as a guide to the end of the canal.

Some Advances in the Office Treatment of Rectal Diseases.—Dr. R. D. MASON of Omaha advocated the treatment of all minor rectal diseases by the use of local anesthesia, using weak eucaine solutions of one-half to one per cent. when injected, and as high as ten per cent. if applied locally to the mucous membrane. He advocated the injection method of treating a certain class of internal hemorrhoids, and described the cases to which it was adapted as those of the old indurated variety in which the tumors were hard and painless, and caused inconvenience more because of their constant protrusion through a loose sphincter muscle than because of any actual suffering. The author also discussed the use of sterile water as a local anesthetic, and showed that it was useless except in tissue where it would be held for a sufficient time to make pressure on the nerve ends and drive out the blood. Because of the large amount of water required, the tissues were so distorted that operation was difficult. A method for divulsing the sphincter under local anesthesia was described. The use of the actual cautery for the cure of hemorrhoids, ulcers and other conditions that needed treatment was discussed, and the technique described.

The Removal of the Uterus for Chronic Inflammation.—Dr. T. C. WITHERSPOON of St. Louis considered chronic retrosalpingitis. He advocated the removal of the chronically enlarged uterus, whose density and vascularity were increased, which, associated with chronically inflamed and altered tubes, caused local and general symptoms that made life burdensome. This was the condition for which, for a long time, he was unwilling to advocate a procedure quite as radical as removal, and did in its place the so-called conservative operation—partial removal of the tubes, resection of the ovaries, correction of retrodisplacements, by various techniques. His results were not good, often not even satisfactory, and for this reason he began to institute a more radical treatment. The starting-point of chronic retrosalpingitis was practically the endometrium. The inflammation might primarily awaken the infectious agents or the predisposition to infection, especially by altered nutrition of the endometrium, the result of repeated congestions, faulty position of the uterus, subinvolution, growths of the uterus or adenxa, or some general infection or constitutional debility. Removal of the uterus brought about entire relief, but much depended upon the technique of the operation. Three things must be imperatively observed: (1) Removal of the uterus with practically all of its endometrium. (2) Avoidance of the large sympathetic pelvic brain, which, with its many central and visceral connections, was situated at the cervicovaginal junction. (3) Complete closure of the peritoneum covering the pelvic floor in order to avoid bowel adhesions. The best technique in the removal of the inflamed uterus was, according to the author, the following: After entering the abdomen by a median suprapubic incision, the tubes were tied off carefully, avoiding injury to the ovaries. A clamp was applied upon either side of the uterus, letting its tip reach well down to the cervix; the body of the uterus was freed from the broad ligament attachments by cutting along the clamps. Amputation was to be performed through the cervix by an exaggerated V-shaped incision, the apex of the V reaching nearly to the external os. The cut ends of the utero-ovarian artery loop were tied, after releasing the clamps, with catgut. The stump was closed, suturing to it the ovarian and round ligaments. All raw surfaces should be covered with peritoneum. Iodine catgut should be used as suture and ligature material. The author felt certain that he had seen considerable reflex irritation from silk and linen ligatures used in tying off the uterine and ovarian arteries *en masse*. The iodine catgut was to be preferred to the cumol gut, in that it resisted infection.

Ligation of the Common Femoral Artery for Large Aneurysm in Scarpa's Triangle; Recovery.—Dr. L. J. DANDURANT of St. Joseph, Mo., reported the case of a man, forty-two years of age, and exhibited patient, who was first seen November 20, 1905. Inquiry revealed a specific infection dating back ten years; also a trauma occurring two years ago in the nature of a horse kick. Examination revealed a large pulsating tumor filling the greater part of Scarpa's triangle, which the author diagnosed as an aneurysm of the femoral artery. He advised the removal of the patient to the hospital and at once began the administration of large doses of iodide of potassium suggested by the specific history. An effort was then made to induce coagulation by compression, with no result whatever from this procedure. He then determined to increase the dosage of the iodide of potassium, and to try the rest cure advised by some writers. Under this treatment the tumor remained stationary for a short time only, and then began to enlarge very rapidly. The author ligated the common femoral artery, without any further delay, just below Poupart's ligament. This was done December 23. From the subsequent history of the case the patient did not present a single untoward symptom. All pain ceased, and the tumor began to decrease in size. The circulation in the leg and foot was apparently not disturbed. They have remained warm ever since the operation, and there has not been a sign of edema at any time. In placing his ligature, he followed the suggestion of Hunter, tying it tight enough to check the pulsation, but still permitting some blood to flow through the tumor. At the end of four or five days, however, this was entirely shut off, and to-day there is a well-organized clot, with perhaps a cavity at its center. The patient left the hospital at the end of five weeks. He succeeded in keeping him quiet a few weeks longer, but at present patient felt no inconvenience on account of the tumor. The author referred to the scarcity of literature on this subject, and to reported cases. He spoke of the importance of conservative management in these cases.

The County Sanatorium for the Treatment of Pulmonary Tuberculosis.—Dr. RICHARD C. MOORE of Omaha said that the indications for the successful management of this disease were surveillance, disinfection, and by appropriate means to increase the

natural power of resistance. These indications could be followed out most satisfactorily by establishing and maintaining sanatoria. He called attention to the statistics of the deaths from consumption in several states, taken from the report of the census of 1900. He believed that a sanatorium in Nebraska would be the means of saving many lives, and would be a center from which information could be promulgated for the early management of such cases, and would thus in time, by instructing the people in prophylaxis and in the home treatment of consumption, greatly reduce the mortality from this cause. Theoretically, the modern treatment of pulmonary tuberculosis could be carried out in the home of the patient, but practically it had been the author's experience that it was impossible to convince the laity, and in fact many members of the profession, that night air was not injurious and that wind, rain, or snow should not be excluded from the apartment occupied by the patient, when by such exclusion the free circulation of pure air was also shut out. To carry out this treatment, the patient must be placed in a suitably arranged apartment, and be absolutely under the constant surveillance of a trained nurse or experienced physician. To accomplish this desideratum, the well-equipped sanatorium was probably the best, but such institutions were very costly to construct, and very expensive to maintain, which rendered them prohibitory in many communities. In Nebraska, where the consumptives, as shown by statistics, were not numerous, the cheapest and most practicable manner of taking care of such cases would be in properly arranged county hospitals. Instead of the ownership and management being under State charge, each county could take care of its own consumptives as it now did its indigent sick and paupers. What was needed to carry out this plan was a well-drained site upon which the county authorities could erect suitable buildings for its tuberculous patients in connection with proper facilities for the culinary department and housing of nurses. The author was inclined to favor a plan similar to that suggested by Dr. Irving Fisher, of New Haven, the main feature of which was an arrangement for ventilation by means of shutters, which were changed automatically with the direction of the wind. Mr. Kimball had given special attention to the construction of tents and wards for the modern treatment of tuberculosis, and had embodied in his plans many valuable and original ideas.

The Expectant Mother.—Dr. E. T. Shelly of Atchison, Kansas, said that the physician owed it to the expectant mother and to himself to give her the best professional attention he was capable of bestowing. As a necessary part of such attention, he should, during the pregnancy, give her such guidance as her condition called for, and to furnish it in a permanent and accessible form. The author spoke of the desirability of supplying the prospective mother gratuitously with an easily understood original pamphlet, issued by the physician himself, and giving her such information as in his opinion, she ought to have in order to pass through her ordeal as comfortably and safely as possible. Such a pamphlet he outlined.

Rachitis.—Dr. A. E. King of Blockton, Iowa, refered to the etiology of rachitis; to the relation to and production of laryngismus stridulus, and spoke of the large number who were afflicted with this disease, and yet whose cases were not recognized by the medical profession. He pointed out the importance of making an early diagnosis, and of instituting proper treatment.

The Surgery of the Paralyses.—Dr. John Prentiss Lord of Omaha said that the education of the general practitioner in this specialty had been limited, and therefore he had too little working knowledge of the benefits to be derived from surgical intervention. The deformities resulting from paralysis were all of a progressive character; therefore, effective treatment instituted before the deformity began would prevent subsequent deformity. It was essential that the general practitioner should recognize that neglected paralysis would surely produce certain deformities, and measures should be taken to prevent or minimize their results. The mere maintenance of a limb in a corrected position not only prevented deformity, but prevented overstretching of muscles which unstretched and treated might be of some service. This was more especially true in spastic conditions. Paralyzed children were entitled to all that science could do for them, and even then the results were small. Oftentimes massage, electricity, bathing, movement, and use would do much in maintaining growth in bone, muscles and ligaments, and limit deformity. The present tendency was to limit the use of apparatus and resort to such surgical measures as would render the limbs most useful. These operations should be judiciously applied to the individual cases, and supplemented by such treatment as would furnish the greatest aid in completing the results. Time was a great factor, and proper knowledge should be displayed lest its proper use be abused and valuable time lost. Reference was made to the great advancement in this branch of surgery; also to nerve transplantation and neuroplasty, or nerve anastomosis.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A Textbook on the Practice of Gynecology. By William Easterly Ashton, M.D., LL.D. Second Edition. 8vo, 1,079 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, cloth, $6.50; half morocco, $7.50, net.

A Treatise on Surgery. By Dr. George Ryerson Fowler. Volume I. 4to, 722 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price per set of two volumes, cloth, $15; half morocco, $17, net.

A Textbook of Materia Medica, Therapeutics, and Pharmacology. By George F. Butler, Ph.G., M.D. Fifth Edition, revised and rewritten by Smith Ely Jelliffe, M.D., Ph.D. 8vo, 694 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, cloth, $4; half morocco, $5, net.

Diseases of the Eye. By G. E. DeSchweinitz, A.M., M.D. Fifth Edition. 8vo, 894 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, cloth, $5; half morocco, $6, net.

The Operating Room and the Patient. Dr. Russell S. Fowler. 8vo, 172 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $2, net.

Nursing in the Acute Infectious Fevers. By Dr. George P. Paul. 8vo, 200 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $1, net.

Essentials of the Genito-Urinary and Venereal Diseases. By Dr. Starling S. Wilcox. 12mo, 313 pages, illustrated, muslin. W. B. Saunders Company, Philadelphia. Price, $1, net.

On Professional Education, with Special Reference to Medicine. By T. Clifford Allbutt, M.A., M.D., F.R.S., etc. 12mo, 80 pages, muslin. Macmillan & Co., New York. Price, 75 cents.

Notes on General Practice. By Dr. S. M. Hebblethwaite. 12mo, 78 pages, muslin. The Scientific Press, London, England. Price, 3/6, net.

Case Teaching in Medicine. By Richard C. Cabot, A.B., M.D. 8vo, 214 pages, muslin. D. C. Heath & Co., Boston.

The Crux of Pastoral Medicine. By Rev. Andrew Kiarmann, A.M. Second revised and enlarged edition. 12mo, 221 pages, muslin. Fr. Pustet & Co., New York. Price, $1.25, net.

Contagious Diseases—Weekly Statement.—Report of cas and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 14, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	390	183
Diphtheria	328	35
Measles	1512	47
Scarlet Fever	220	20
Smallpox	5	
Varicella	93	1
Typhoid Fever	30	10
Whooping Cough	34	6
Cerebrospinal Meningitis	41	30
Malarial Fever		
Totals	2,653	332

Human and Bovine Tuberculosis.—Valée and Carré have completed certain researches in this line of work undertaken by Nocard. In the first experiment a cow free from tuberculosis was inoculated in the udder with a culture grown on potato, of human bacilli recently isolated from the sputum of a tuberculous patient. During the following year the only results noted were a change in the milk and a slight induration of the mammary region inoculated. From the thirteenth month the bacilli appeared to become adapted to their new quarters, and a serious tuberculous mammitis developed. Four calves who at two different times had drawn milk from this infected udder contracted an extensive abdominal and pulmonary tuberculosis. At the end of the twenty-second month of the experiment the inoculated cow was killed. Besides the tuberculous mammitis, there were found specific abdominal and pulmonary lesions. The human bacillus that had been inoculated was previously recognized by Nocard as lacking in the qualities pathogenic to cattle. In the second experiment a monkey swallowed a small quantity of very virulent culture of bovine tuberculosis. This same culture, inoculated into the udder of a cow, killed the animal in thirty-two days. The monkey contracted a generalized tuberculosis, from which it soon died. The bovine bacilli which lodged in the mesenteric ganglia of the monkey lost their virulence for the cow. They had to be passed successively through the udders of two milch cows in order to partly regain the initial virulence for cattle. The culture finally killed a third cow in sixty-five days after inoculation. These experiments established clearly the fact of the ease with which the bacilli of Koch are changed, and also their faculty of adaptation to species of animals other than those from which they are taken.—*Le Bulletin Médical.*

To What Extent Should Insurance Organizations Educate Their Insured as to Healthful Living?— E. S. Sherrill calls attention to the statistics concerning 5,379 deaths. He gives a list of well-known diseases represented in this mortality—typhoid fever, malarial fever, consumption, diabetes, apoplexy, organic heart disease, angina pectoris, pneumonia, liver and gall-bladder diseases, appenditicitis and peritonitis, and Bright's disease Here is a total of 3,093 deaths, nearly 60 per cent., from these diseases. The writer believes that a physician of fair ability who could have had the oversight in a somewhat authoritative way of the lives thus ended could have made a very great change in the death rate. Many of the deaths were due to preventable diseases. These cases cited are selected lives. The five hundred who died from tuberculosis are supposed to have shown no trace of the disease at the time of examination. The German Sick Benefit Societies find it an actual financial advantage to send members to sanatoria for treatment for tuberculosis rather than pay them sick benefits at home. Fraternal insurance in this country is following the example. The project developing at Las Vegas, the writer thinks, will doubtless prove equally advantageous. He believes that insurance organizations should enter upon a careful plan of instructing policyholders along lines which will tend to lengthen life expectancy.—*The Medical Examiner and Practitioner.*

Epidemic Mumps and Whooping-Cough.—Paolo Galli calls our attention to the statement of Bernardone that parotitis and pertussis may possibly be antagonistic. He has observed some evidences of such antagonism. The author records the history of an epidemic of parotitis coincident with one of pertussis observed by him at Faenza. Where the parotitis existed the pertussis did not appear in some districts, and vice versa, so that the two diseases seem to confer a temporary immunity against each other. In other districts the pertussis was very mild in character after the parotitis had occurred, in many children. Hence the author thinks we are justified in saying that mumps has favorably influenced pertussis in some cases, but that more observations are necessary before we come to any definite conclusions.—*Rivista Critica di Clinica Pediatrica,*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending April 14, 1906:

THE ETIOLOGY OF RELAPSES IN SYPHILIS.*

By J. NEUMANN, M.D.,

VIENNA, AUSTRIA

ALTHOUGH syphilis is one of the best known diseases and has been made the subject of many researches both from its anatomical and from its clinical aspects, one of its most characteristic peculiarities, its relapses, using the term in its widest sense, has not yet been explained adequately from an etiological point of view. It is, therefore, easy to understand that the origin, the localization, and period of occurrence of syphilitic relapses should be made the objects of frequent researches. The subject has recently been discussed by Lesser,[1] and the case which served as the text for his disquisition as well as the practical conclusions to be drawn from it have impelled me to take up the matter again although I have already on several occasions spoken of it. In my last study in this connection,[2] the theories of the etiology of the relapse in syphilis are discussed and their pros and cons set forth in detail.

In regard to Virchow's hypothesis, quoted by Lesser which was probably the first theory founded on an anatomical and clinical basis, it must be admitted that it cannot be regarded as absolutely correct even for the earlier relapses in which a contamination of the blood stream can be taken for granted, the condition which Virchow evidently had in mind, since his theory assumed that the lymph glands formed the main repositories of the syphilitic virus from which intermittent infections of the organism took place. For relapses often occur in syphilis without demonstrable swelling of the lymph glands, and enlarged glands often persist for long periods of time without any relapse. But although there is no doubt that syphilitic glands are foci of virus from which this may penetrate into the juices of the body and evoke a new eruption in any region, repeated histological researches have demonstrated that every portion of the body which has been the seat of a well developed syphilitic product retains the residua of this, and during many years, like the lymph glands, may serve as a depot of virus which, under suitable conditions, may give rise to a relapse *in situ* in the neighborhood, or in a more remote region. The traces of syphilitic products which persist after the disappearance of the clinical manifestations are the only demonstrated sources of the temporary contamination of the blood, that is, of the relapse. This has been proven through relapses *in situ* which are sometimes often repeated and which may occur in consequence of definite irritations, or spontaneously. That these deposits in the course of the disease may diminish and finally completely disappear is in accordance with their biological character. In this way a sufficient explanation is furnished of the progressive diminution in frequency and intensity of the lesions, the unsymmetrical nature of the manifestations, the diminished or totally lost virulence, and the entire disappearance of relapses which is in proportion to the period of duration of the disease. I wish to emphasize the fact that the syphilitic lymph glands owing to their structure and function are especially well adapted to be repositories of the syphilitic poison. Lesser makes the following objection to this and to Virchow's theory: "If we regard only the manifestations on the skin, which are the most conspicuous and therefore the best known, the typical course of events is that at first a symmetrical exanthem appears, which in the beginning is spread over the entire or almost the entire body but is later on followed by less extensive but still symmetrical relapses, until finally, in the latest stages, isolated, unsymmetrical lesions appear. If these relapses are produced by the liberation of the poison contained in certain foci why do not the later and latest lesions display the extensive and symmetrical localization of the first eruption, which is formed as the result of the universal dissemination of the poison present in the circulating blood?" Without reflecting on Lesser's emphasis on the symmetry of the first and earlier syphilitic eruptions, I should like to remark that this argument would justify the conclusion that in time the syphilitic virus, quantitatively and qualitatively, and also the conditions of origin of the syphilitic manifestations, have undergone an alteration which would lead to the asymmetry and isolation of the lesions which are referred to by Lesser. It does not prove, however, that, so long as a relapse *in situ* is not in question, the virus causing the unsymmetrical and isolated lesions cannot arise in a neighboring or more or less distant lymph gland. It is not necessarily, but may be the case that the syphilitic virus may remain longer precisely in the lymph glands until through some cause it passes into the lymph stream, so that it seems plausible to believe that the lymph glands may also have their part in the virus which gives rise to the late relapses, if they do not furnish it entirely. Very remarkable and difficult to explain are those relapses which sometimes occur after a free interval of one or more decades. It must be admitted, however, that the existence of latent intervals of ten, fifteen, or more years has not been indubitably proven. Syphilitic symptoms may entirely escape even the most careful observation, provided this is not continuous in the strictest sense of the word, or their specific nature may not be recognized. This is especially true of symptoms which are frequently found in other conditions, such for example as anemia with all its concomitants and sequelæ, or visceral affections which, although

*Address delivered before the 15th International Medical Congress, Lisbon, April 19-25, 1906.

depending on a syphilitic basis, may be ascribed to other causes. Furthermore, manifestations unaccompanied by striking symptoms may attract the patient's notice but slightly or not at all and disappear spontaneously, so that they never come under medical observation. There is no doubt that the putative long periods of latency arise in this way, although I would not deny their existence absolutely. Unna's theory which considers every syphilitic relapse as a relapse *in situ* does not help us over the difficulties attending the solution of the question of periods of latency lasting three, ten, fifteen, or more years. It may, in addition, be regarded as an accepted fact that relapses occur also in portions of the body where no lesions occurred originally, although the relapse *in situ*, as I long ago and since then frequently have noted is much commoner than was generally considered formerly or even at present. I believe that in order to demonstrate the frequence of relapses *in situ*, which is of importance for the present question, the procedure advocated by Hjetman is to be warmly recommended, at least for the organ that is most suited to it, the skin. The dicta of Lang which are also cited by Lesser are, as a matter of fact, deductions from the clinical course of the syphilitic process in its most pronounced phases. An objective explanation of the pathogenesis of the syphilitic relapse, especially the late relapse after very long periods of latency, is, on due consideration, not afforded by them. If, in view of Schandinn's observations, one considers the powers of resistance and the length of life and of virulence of many pathogenic organisms—that, for example, the spores of anthrax after remaining in the soil for more than ten years entered the animal body again may unfold their full activity; that Hjelmann was able to demonstrate pathological products in the excised scar of a chancre of the frenulum thirteen and a half years after infection—it does not appear astonishing that the organism of syphilis after years of inactivity in an encapsulated, inveterate, syphilitic focus under the influence of favorable conditions may reacquire its former virulence, multiply, and, becoming active again, give rise to new lesions. That at the present moment we are unable to offer an explanation of the origin of late relapses of syphilis is, as Lesser has correctly observed, owing to our ignorance of the nature of the syphilitic virus and the causative agents of the disease. But I should like to point out that in the chronic infectious diseases, especially in the one which presents the closest analogy to syphilis, tuberculosis, in spite of our more accurate knowledge of the causative agent the explanation of the origin of the primary infection and of the relapses is still far from complete. So long as we remain in ignorance of the relations of the incitants of disease to the biological processes of the body we shall be unable to solve these questions in a satisfactory manner.

In regard to Lesser's case I refer to my observations[3] on the histological findings, in which the persistence of pathological products after the disappearance of the manifest clinical alterations has been proved in unimpeachable fashion. Lesser's case and that of Jadassohn cited by him, as well as one of Lesser's in which the roseola rings surrounded the areas of leucoderma on the neck, impel me to refer to an observation that I have repeatedly made and called attention to: that the anatomical changes persisting after the disappearance of the clinical manifestations usually extend far beyond the area of the changes visible externally. In consequence of this the cases cited are practically relapses *in situ* in which a distribution beyond the original area limits may have taken place. Jadassohn's statement, "one receives the impression that a virus is distributed irregularly from the central focus," is a fact that has been established by my own microscopical studies and later by those of others. The irregularity is due to the fact that the larger portion of the disease germs is buried in the adventitia and in the perivascular spaces of the irregularly disposed vessels.

In passing it may be remarked that in cases of relapse *in situ* the deeper situation which heretofore has been considered as characteristic for the late syphilitic relapses in general—for the skin in the subcutaneous tissues, for the mucous membrane in the submucous tissues, for the periosteum in the superiosteal tissues—is to be explained on the ground that in the recent syphilitic product the histological changes also extend deeper than might be inferred from the clinical manifestations.

In regard to the objection that has been made, "that if all the relapses, including the isolated and unsymmetrical ones occurring in the latest stages, are produced through a new infection of the blood from encapsulated foci, why do not the later and latest relapses exhibit the extensive and symmetrical disposition of the first eruption?" it may be said that for the production of relapses *in situ* circulation of the syphilitic virus in the blood is not necessary. That local stimuli, even of a purely functional nature, may suffice to effect this is a well-known and universally recognized fact. In this connection, I refer again to the relapses occurring in the mouth and pharynx where, in consequence of mechanical, chemical, thermic, and functional irritations, not only the cure of the syphilitic manifestations is protracted but the relapse *in situ* is also a common occurrence. In those portions of the mucous membrane which were occupied by a circumscribed erythema or in the immediate neighborhood, a papule is formed which later becomes an ulcer, and after the cicatrization of this, sooner or later a gumma forms, as has been shown by observations. I recall the cases of Portalier,[5] in one of which an ulcerative syphilide relapsed during five years in the same spots, in another a psoriasis palmaris returned again and again during ten years in a physician who had infected his finger. In the same connection I would mention an interesting case recently reported by me in which the original lesion formed papules on the posterior pharyngeal wall. During a space of five years at varying intervals ulcers appeared at the same spot followed by ulcerating gummata which destroyed the soft parts and then the anterior segments of the three upper cervical vertebræ until the cervical cord become involved and death resulted. In cases of late relapses *in situ* it follows from what has been said that there is no difficulty in explaining the asymmetry and the singleness of the lesions. But, as I have already observed, my clinical experience shows that on the skin, which is the most studied and most accessible organ, late lesions also occur in places in which originally no syphilitic manifestations developed, although, as I should like to point out, the latter in most cases are relapses *in situ*. Among forty-eight women who had chancres of the cervix and who came repeatedly under observation on account of various conditions, twenty-five, or fifty-

six per cent., in the space of from a few months up to fifteen years, had relapses which were located in the situation of the primary lesion. This figure might be considerably increased if only the relapses occuring five, ten, or fifteen years after the infection should be considered. Nevertheless there remains a considerable number of late relapses which are situated in regions where originally there was no syphilitic lesion. Such relapses as these are far from easy to explain in regard to their localization, singleness of occurrence, and special conditions of formation. I consider that Lesser's view in this respect deserves quotation verbatim: "Accordingly we assume that in the eruptive stage of syphilis the entire body is flooded with the virus of the disease; that then portions of the poison remain at first in a uniform manner in numerous parts of the body from which, in the further course of time, relapses originate, but that the longer the interval that has elapsed since the infection more and more of these remaining germs perish and finally disappear entirely. This affords a ready explanation for the fact that . . . the first relapses are numerous and are symmetrical, but that as time passes the eruptions become scantier and more irregular in distribution, in conformity with the isolated location of the germs that still exist and develop. If, finally, very late relapses occur, these are usually solitary or form only a few foci because only very few germs possessing vitality still remain." From this it may be seen that Lesser agrees with Unna in regarding the late relapses of syphilis—or to use the ordinary terminology, the tertiary lesions—as newly developing remains of old syphilitic products persisting from the years of the secondary or even of the primary stage. This view, which, in its essentials, has already been expressed by me,[6] is, strictly speaking, true only for relapses *in situ*. In the formation of relapses of the other category, the metastatic variety, probably the remains of the early syphilitic products also furnish the carriers of the syphilitic germ, but these must first effect an entry into the lymph or blood circulation, and must possess a degree of virulence which renders them capable of producing a new lesion when present in sufficient numbers on suitable soil.

The following considerations show that the germs of the metastatic relapse are formed rather by the remains of the early syphilitic lesions persisting for years, than by a circulating syphilitic poison continuously present in the blood or tissue juices. If there were continuously present in the blood syphilis germs in such quantity and of sufficient virulence to be able to produce syphilitic lesions in any portion of the organism, then some syphilitic manifestation would have to be present in the body at all times. This, however, is not true as has been shown by the most careful observations. Virchow, himself, has said[7] that "the conception of a chronic dyscrasia by no means involves the necessity that the blood at all times contains disease products; on the contrary periods of infection and periods of freedom from this (in the blood) may alternate with each other." I should not like to affirm that in the latent periods, even after the first two years following infection, the blood stream is absolutely free from syphilis germs, but I assume that during the period of latency any germs that may be circulating in the blood stream are not capable of evoking a lesion in the body *itself*, either through quantitative or qualitative weakness or both of these together. When I say in the body *itself*, I do this in view of the frequently observed fact that a pregnant woman with latent syphilis who does not exhibit any symptoms of the disease during her pregnancy brings forth syphilitic offspring. This fact that from the blood stream of the mother with latent syphilis, germs which have passed into the fetus may produce severe lesions although they do not give rise to any manifestations in the body of the former; the fact that individuals with latent syphilis who do not display any symptoms may transmit syphilis through an inconspicuous fissure by contact, causing a typical chancre to develop; that, therefore, germs which in the first organism were unable to produce a lesion evoke typical changes in the second, among other things lead to the conclusion that in the tissues themselves certain conditions must exist in order to cause a syphilitic lesion to be developed. This is what is ordinarily called "a predisposed or suitable soil" also "*locus minoris resistentiæ*, lessened resistance," but this is only an excuse for our defective knowledge. The conditions which control the localization of the metastases in a single organ or portion of an organ are still unknown—which, by the way, is also the case in other infectious diseases. I have mentioned these facts because they serve as sign posts in the darkness of the origin and the localization of the scanty and isolated appearance of the metastatic, late relapses of syphilis. As I have already expressed my opinion concerning the value of deductions from analogy, and have therefore protected myself against the accusation of regarding these as adequate proofs, I observe that if we keep in mind for example the route which the syphilis germs must travel in their passage from the organism of the mother into that of the fetus we shall come to the conclusion that there is justification for the view that syphilis germs which have entered the blood stream from some residual focus are capable of traveling long distances in the body. In this way the first condition of the production of metastatic relapses of syphilis is shown to be a possible and real occurrence; furthermore these facts indicate that the small amount of the syphilis germs which pass into the blood from the residual foci is probably the chief cause of the scanty and isolated appearance of metastatic, late relapses; but it is not the only cause, for, as has been stated above, in the case of an infection produced by a small fissure on the lip of an individual with latent syphilis the number of syphilis germs transmitted—which still is able to produce a chancre at the place of contact—is very small, while the much larger number of germs present at the same time in the infecting organism does not give rise to any manifestations. There must, therefore, exist in the tissues themselves certain conditions, and this is the second factor in the explanation of the asymmetry and singleness of late syphilitic relapses.

If, furthermore, we consider the well-known fact that in individuals with latent syphilis a syphilitic lesion is to be produced by inoculation even with highly virulent syphilitic secretion only after the application of considerable irritation—that is the production of suitable conditions in the tissues—it will be apparent that in an organism which has for a long time been the seat of latent syphilis the situations in which the conditions necessary for the development of a syphilitic product exist are few and far between.

Herewith I believe that I have explained as

well as possible and in the briefest form the questions constantly arising in the nosology of the relapse of syphilis, especially in late syphilis. The evidence furnished by the histologically demonstrated cell-rests as persisting signs of healed syphilitic lesions has been recognized by the majority of authors. Only isolated writers deny this testimony, such for example as Caspary,[8] who, in discussing persisting signs of hereditary syphilis, has stated that my teaching required corroboration. In opposition to this, Galewsky, Rille, and Meissener have brought forward further proofs in favor of my explanation of the relapse in syphilis. Galewsky has laid stress on the development of late manifestations in old scars, particularly at the site of the chancre, as has now been universally recognized. Meissener points out that in syphilitic infection shortly after the appearance of the primary lesion, before the development of the roseola, the vessels in cutaneous areas far distant from the chancre already show changes which disappear again after antiluetic treatment. It is true that Jadassohn considers that the assumption of residua is not necessary in the explanation of local relapses, believing that the well-known facts of provocation suffice in this respect, and says that scars also are more easily affected by irritation and may give rise directly to the provocation. Jadassohn has often found collections of cells in old scars, but affirms that ordinarily we have no criterion for the cell infiltrations occurring in normal skin.

This question is closely associated with that of the duration of the infective stage in syphilis, a topic which was discussed at length in the Third International Dermatological Congress in London in 1896. Hutchinson believes that it has been proven that, during the primary and secondary stages the blood and all other secretions contain the syphilitic virus and that transmission to other persons is possible. He considers that after two years have elapsed the syphilitic poison has disappeared from the tissues and fluids of infected individuals, and the danger of transmission is over. He permits patients to marry two years after the appearance of the chancre, and usually does not pay much attention to moderate relapses appearing after this time (!). Hutchinson mistrusts in general the reports to the effect that a man has transmitted syphilis to his wife ten or even more years after infection. The period of hereditary transmissibility appears to be longer in women than in men, and the ability to transmit infection also appears to persist longer in women. He also believes that hereditary or general transmission during the tertiary period, excepting in extremely rare cases, is out of the question. This view of Hutchinson's must now be regarded as incorrect. The same author considers that mercury attacks the syphilitic virus directly and destroys it, and that secondary symptoms appear when the administration of the drug is interrupted. Campame calculates the period of infectivity of a syphilitic individual as three years. Lassar[9] is of the opinion that the question of contagion has not been sharply enough differentiated from that of infection. Contagiousness in syphilis may be lost without effect on the infectiousness, although the reverse is hardly likely. From a single papule an indefinite number of infiltrations may result, which probably can be explained only on the assumption of permanence of infectiousness. In view of the different forms of the disease it is almost impossible to determine in what stage a given patient may be. There is much in favor of the view that infectiousness lasts throughout the entire course of the disease, although on the other hand it cannot be denied that the danger of contagion decreases as the disease progreses. Several observations made by Lessar prove that syphilis may remain contagious even in very late stages; for example, transmission being reported ten, twelve, fifteen, or sixteen years after infection. The problem of the capacity for infection in syphilis has not yet been solved. Feulard has stated that he does not counsel marriage to a syphilitic before the expiration of the fourth year, and that in rare instances hereditary transmission has occurred ten years after infection. Tarnowsky was able in a series of 1,000 syphilitic patients to demonstrate typical specific symptoms in 802 during the first five years after infection, in 176 after the first five years, in 26 after ten years, and in 5 after fifteen years. A syphilitic individual can therefore transmit the disease fifteen years after infection. Blaschko has observed a case in which a husband infected his wife five and a half years after acquiring a chancre.

These observations accordingly appear undubitably to explain the occurrence of relapses. The proliferated cells are, however, to be regarded only as the carriers of the virus and not as the virus itself. Through the discovery of *Spirochæta pallida* by Schaudinn the entire question has received a positive basis, and it will not be difficult in future to extend ther esearches that heretofore have been devoted to pathological products, to the study of the spirochetes. In this way the hopeful prospect is afforded that in the future one of the most important questions—that of the nature of the relapse—may be solved.

Conclusions. (1) The late syphilitic relapses, the relapse *in situ* as well as the metastatic relapse, have their origin in the microscopically demonstrable syphilitic products, including the syphilitic lymph glands, which persist after the disappearance of the clinical manifestations. These may exist a very long time, even more than a decade.

(2) The complete elimination from the organism of all the germs of the disease as promptly as possible therefore follows as a fundamental indication in the treatment of syphilis.

Trachoma and Its Treatment. — Cornelius Williams declares that trachoma flourishes in any place in which there is crowding and lack of cleanliness. He condemns the application of crystal of copper sulphate in the treatment of this affection, preferring the silver nitrate method, since it has given better results in his experience than any other remedy. He believes it advisable to suspend the use of the silver salt now and then, substituting for it a very weak solution of iodine in saline solution, with the addition of iodide of potassium.—*St. Paul Medical Journal.*

HEPATIC INSUFFICIENCY

ITS CAUSES, RECOGNITION, SIGNIFICANCE, AND TREATMENT.

By ALFRED C. CROFTAN, M.D.,

CHICAGO, ILL.

Whenever an organ fails to perform its functions properly we say that it is insufficient. This term may denote both qualitative and quantitative variations from the normal. The more complicated and the more active the functions of an organ the more liable it is to insufficiency. The liver, therefore, possessing as it does the most manifold functions of any organ of tne body, is particularly subject to functional derangements. Its exposed situation, moreover, and the peculiar arrangement of the four systems of capillaries that form an intricate labyrinth around and through each hepatic cell render the latter especially liable to injury by circulating toxins. These poisons reach the liver cells continuously from the general circulation in the hepatic artery, through the lymphatic circulation (especially from the peritoneum), the portal circulation and the bile channels.

Causes.—One may differentiate for clinical purposes between mechanical, parasitic, and toxic causes of hepatic insufficiency, remembering always that the three may be and usually are correlated and intimately connected.

Chief among the *mechanical causes* are all sclerotic changes causing overgrowth or contraction of interstitial liver tissues and thereby producing mechanical compression of liver cells or of their afferent blood-vessels. Then there is mechanical stenosis, occlusion or obliteration of large blood-vessels by embolism, thrombosis, or pressure from without, causing similar nutritional changes, and later, necrosis of large areas of liver cells. Again, the bile ducts of the liver may become similarly narrowed or occluded by biliary concretions or by the invasion of these channels from without by parasites and in either instance producing stagnation of bile and mechanical compression of liver cells or of the blood-vessels that nourish them. Finally, certain heart lesions must be included among the mechanical causes, for, by producing stasis of venous blood in the capillaries of the liver, they too exercise mechanical compression upon the hepatic cells and cause derangement of their function.

As has been intimated, the *parasitic causes* of hepatic insufficiency occupy an intermediary position between mechanical and toxic causes, for any microorganism that invades the liver channels or the liver tissues proper may act either as a foreign body by mechanically destroying liver cells by pressure or by occluding the blood-vessels or bile channels, or it may lead to the formation of chemical poisons that intoxicate the liver cells.

The *toxins*, finally, that can produce hepatic insufficiency are so manifold that it would be useless to attempt to enumerate them in this place. It is sufficient to say that all the poisons generated in the bowel, the spleen, or the pancreas must travel first to the liver before they can reach the general circulation beyond; that all the manifold array of metabolic poisons that can be formed in the system at large always come into particularly intimate contact with the liver cells owing to the intricate interlacing of the capillaries of the hepatic artery and the hepatic lymph-channels in the liver. Finally, the liver, possessing as it does a most active metabolism of its own, continually manufactures toxic intermediary bodies within its substance; and this is particularly the case if its function is in any way derang d.

Symptoms.—The changes that the liver may undergo as a result of all these causes may vary from mild transitory functional derangements to destructive histological lesions of the hepatic cells. The symptoms of hepatic insufficiency are, therefore, very numerous. This is self-evident when we consider the many functions of the liver, any one of which may become qualitatively or quantitatively perverted. Our knowledge of the finer mechanism of the intermediary metabolism going on within the liver is, however, still so woefully incomplete that it is unfortunately well nigh impossible to interpret slight derangements of many of these functions correctly. For this reason we are as yet unable to recognize as early as we might wish the first manifestations of hepatic insufficiency, as we can, for instance, recognize early functional changes of the kidneys in the urine, or mild derangements of the stomach function in the gastric contents long before anatomical lesions supervene. From the standpoint of prophylaxis and therapy this is particularly deplorable.

In order to understand the symptomatology of hepatic insufficiency it is necessary to have a clear understanding of liver physiology, because it is manifestly impossible to understand the pathology of any group of functions unless we understand their physiology, to appreciate or correct the abnormal until we understand the normal.

The normal function of the liver may be summarized under the following five heads: (1) formation of urea, (2) conversion of sugar into glycogen and the storage of the latter, (3) formation of bile, (4) elaboration both by anabolism and catabolism of circulating radicals of the fats and albumen, (5) general disintoxication of circulating poisons and the formation of antitoxic bodies. Perversion of these five mentioned functions must lead to the following results:

(1) A diminution of the circulating urea and a flooding of the blood-stream with bodies that have failed to undergo conversion into urea in the liver, notably ammonia salts and amido-acids, with the appearance of corresponding urinary symptoms, *i. e.* a decrease of the urinary urea and a corresponding increase of the urinary ammonia and amido-acids.* At the same time, as urea is the most potent physiologic diuretic, a decrease in the amount of urine.

(2) Owing to the inability of the liver to convert sugar into glycogen and to store the latter, a flooding of the blood-stream with an excess of sugar that is derived from the ingested sugar or starches, with resulting hyperglycemia and glycosuria. This condition may be obscured if the patient does not happen to have eaten much starch or sweet foods, but it should readily appear, even in mild degrees of hepatic insufficiency, as an *alimentary glycosuria* if the patient is given appreciable quantities of starch or sugar in the food.

(3) The inability of the liver to form bile leads to numerous serious consequences that have already been indicated above. Chief among these is stasis of bile with the biliary channels and as a result diapedesis of poisonous bile constituents from the bile-capillaries into the blood-capillaries, in other words icterus. In this connection a very important point should be mentioned, viz., that jaundice occurs only in relatively mild degrees of hepatic insufficiency, whereas in very severe degrees jaun-

*See also "An Analytic Study of Uremia"—*Journal of the American Medical Association*, January 6, 1906.

dice can not possibly occur for the reason that the liver cells no longer form bile. Here the intoxication is especially severe because the products that should normally be disintoxicated by the liver and excreted into the bile pass through the liver cells unchanged and are returned to the circulation in a highly toxic form. This condition has been called by the French *grande insuffisance hepatique*. Another result of failure of the liver cells to produce a normal amount and the normal kind of bile is interference with the function of the upper portion of the intestinal tract. The withdrawal of the bile or the entrance of abnormal bile into the bowel allows intestinal fermentation to go on unchecked, renders the normal emulsification of fats impossible, and produces numerous other results that have been enumerated above. At all events the withdrawal of normal bile from the bowel in itself causes an increased flow of toxic bodies to pour into the liver through the portal vein and the intestinal lymphatics, and hence promotes the causes that produce hepatic insufficiency. The derangement of the bile-forming function therefore produces a vicious circle that is highly dangerous.

In the urine this condition usually becomes manifest by an increase *of the aromatic sulphates*, notably *indican* and the appearance of *urobilin bile pigments*, and *bile acids*.

(4) Failure of the liver to perform properly its share in the metabolism of the albumin and fats causes fragments of the latter to be returned to the circulation, either unchanged or disassimilated into abnormal products. This, too, produces a general intoxication and may, in its ultimate consequences, lead to a syndrome that is not distinguishable from uremia, that is, moreover (as I have attempted to show recently), in all probability *uremia* (Croftan 1. c.). Here the urine contains abundant *ammonia salts*, relatively *small quantities* of *urea* and usually an abnormal amount of *fatty acids* possibly of *leucin* and *tyrosin*.

(5) The loss or reduction of the normal disintoxicating power of the liver finally is the most serious result of hepatic insufficiency and usually constitutes a terminal stage of the affection. Here the portals are thrown wide open to the invasion of the body with poisons of a thousand kinds that are formed in the bowel and in the tissues at large. That the organism cannot long withstand this toxic flood is self evident. In such cases that *toxicity of the urine* will be found to be enormously *increased* while, at the same time, the kidneys invariably became affected, for, upon them is now thrown the task of ridding the body of circulating poisons, a function that normally they shared with the liver. When renal insufficiency complicates hepatic insufficiency a severe toxemia must develop in very short order, and again a fulminating syndrome is presented that closely simulates uremia.

Treatment.—The treatment of hepatic insufficiency may be considered under two headings: (1) The suppression of its causes. (2) The symptomatic treatment of its manifestations.

Causal treatment is in most instances synonymous with prophylaxis. Three factors, as I have mentioned above, chiefly determine insufficiency of the liver cells, *i. e.* infection, intoxication mechanical causes.

The latter, unless we are dealing with some lesion that mechanically compresses a common duct and that can be removed surgically, is not amenable to treatment so that in this instance we are limited to symptomatic therapy. There is an exception to this rule, *i. e.* syphilis. Here we may be dealing with a gumma located in such a way that it produces compression of a large bile duct or of an important blood-vessel, or we may be dealing with a syphilitic interstitial hepatitis. In both of these instances anti-syphilitic treatment may remove the cause, mechanical though it be. To an extent this also applies to what may be called mechanical hepatic insufficiency due to venous stasis in the liver following heart lesions. Here cardiotonic treatment may cause the symptoms of hepatic insufficiency to disappear.

In the case of the intoxicating factors the source of poison is in the overwhelming majority of cases the gastrointestinal tract. Here causal treatment should be carried out according to the following principles: To regulate the diet in such a way as to limit the ingestion of substances that are in themselves poisonous or that undergo changes in the bowel that lead to the formation of poisonous bodies; to reduce to the lowest possible minimum intestinal putrefaction; to prevent as far as possible the absorption of whatever poisonous bodies may have gained entrance to the bowel or may have been formed there; to promote the destruction of the latter in case they enter the circulation, and above all to hasten the rapid elimination of circulating toxins. The latter indication prevails with equal force in the case of poisons that are not formed within the bowel, but that are generated within the tissues of the body (endogenous poisons) as in infectious diseases and in a variety of metabolic disorders.

Under the head of causal treatment all those measures might also be included that we know are capable of stimulating the hepatic cells to renewed activity when their energies begin to flag, but this treatment must be carried out with conservatism, as I will have occasion to show further on.

Symptomatic treatment includes the treatment of the protean array or sequelæ of hepatic insufficiency. As derangement of the liver function in its ultimate consequences may lead to the greatest variety of psychic, nervous, cardiovascular, renal, and metabolic disorders, symptomatic treatment of hepatic insufficiency in the broader sense covers a large field of therapy. I had occasion to show in a recent article that intestinal putrefaction, by producing hepatic insufficiency may be considered one of the main causes of a great variety of chronic diseases involving almost every tissue and organ of the body. This trite statement has been preached by medical investigators since time immemorial. Such words as hypochondriasis and melancholia, meaning as they do etymologically "under the ribs" and "the black bile flow," and introduced into medicine by the physicians of ancient times, indicate clearly how well these old doctors recognized the important rôle of the liver in the production of psychic phenomena, and nowadays we know that autointoxication from the bowel chiefly by deranging the liver function can exercise a most profound influence upon the kidneys, the heart and arteries, the general metabolism, and the nervous system. I will limit myself in this place to a brief discussion of the dietetic treatment, the use of certain physical means and the use of certain remedies, including organotherapeutic measures, that can meet the indications formulated in a general way above.

Dietetic Treatment.—Probably the most important dietetic rule in the treatment of hepatic insufficiency is a negative one, *i. e.* that all alcoholic beverages should be rigidly excluded from the diet. There is much exaggerated prejudice

in the minds of physicians and the laity in regard to the dangers of alcohol in most diseases. Alcohol constitutes a very valuable remedy, and, in a sense, a food. But we do not realize sufficiently that pure ethyl alcohol is the least toxic of all the alcohols that are used in the food of man. The higher alcohols and certain aldehydes and essential oils that are found in cheap liquors and that bestow the aroma or bouquet upon the various wines, liquors, and cordials are much more poisonous even in the small quantities in which they are used; thus *e. g.* absinthe contains some eleven different principles all of which are poisonous. Alcohol itself, therefore, unless taken in enormous quantities is not so terribly dangerous, but no one drinks pure dilute alcohol but rather alcoholic beverages of various kinds and as the latter are poisonous on account of the impurities they contain, it should be a cardinal rule in the treatment of hepatic insufficiency to exclude them rigidly from the diet.

On the same grounds spices and condiments should always be excluded because they contain essences of alkaloids that are toxic to the liver.

A second cardinal rule is to limit the ingestion of fats, for they are very poorly digested owing to the deficiency of bile acids from the bowel; it is clear that in this case, as stated above, they are not properly saponified and emulsified, undergo rapid decomposition in the bowel, and in this way lead to the formation of acid and acrid products that are highly irritating to the liver and the bowel. It has been shown that in cases of hepatic insufficiency the urinary toxicity increases greatly when much fat is given. While it is not necessary, therefore, to exclude the fats altogether from the diet, they should be reduced to a minimum.

Meat and eggs should also be reduced, for they furnish the bulk of the most toxic intestinal products whenever intestinal putrefaction goes on unchecked and this we know to be the case when the bile is deficient or its composition is changed.

There remain, therefore, as chief articles of food, vegetables and carbohydrates; the latter, in particular, are not toxic nor do they lead to the formation of toxic bodies in the bowel; and besides, sugar, as we know, stimulates the liver functions to activity. Of course, care should always be exercised not to administer a diet containing too large a proportion of carbohydrate food for otherwise fermentative dyspepsia, constipation, and a variety of digestive disorders may supervene. One should simply increase the amount of carbohydrate food to replace the deficit of fat. Milk can always be given with impunity. An exclusive milk diet, however, is for many reasons objectionable.* To summarize, the patient should be placed upon a bland mixed diet, containing no alcoholic beverages, a minimum of fat, a small amount of albuminous food, and plenty of fresh fruits, vegetables, milk, cereals, starches, and, with care, sweets. That the details of this diet should be regulated in such a way as to consider individual idiosyncrasies and tastes, and above all complication in other organs, notably the kidneys, need hardly be emphasized.

Medicinal Treatment.—In view of the fact that the chief source of the poisons that intoxicate the liver and produce hepatic insufficiency is the intestinal tract, it is of paramount importance to attempt *intestinal antisepsis* in every case of hepatic insufficiency that comes under observation. This is especially necessary early in the disease before the liver cells have undergone anatomic changes. It is impossible within the narrow frame of this article to discuss the means at our disposal for promoting intestinal antisepsis. We are unable, of course, to render the long intestinal tract completely sterile, nor is this desirable for many of the saphrophytes that abound in the normal bowel contents play an important rôle in disassimilating the food elements. In this way they undoubtedly aid the normal digestive ferments in degrading complicated bodies into simpler assimilable substances, moreover, they produce by gas formation or liquefaction certain physical changes in the bowel contents that favor normal peristalsis and the act of defecation. All that we can attempt to do is to hold in check the pullulation of virulent and putrefactive bacteria, and this object, I believe, can be accomplished by a number of remedies.

That the absorption of bowel poisons after they have once been formed can be restricted by the use of evacuants is clear. A saline laxative given at frequent intervals, combined possibly with enemas to clean out the lower bowel, is a useful measure. Purgatives or drastics that can irritate the liver should be used cautiously.

All attempts that have so far been made to promote the destruction of poisons after they have once been absorbed have been abortive. A. Robin, as is well known, introduced a so-called oxidizing treatment and advised the inhalation of oxygen, the use of iron and manganese preparations. I have never seen any tangible good results follow this treatment. Cold hydrotherapeutic measures, thanks to the leucocytosis, the increased metabolism, and the better circulation of lymph they produce, are of much use.

The elimination of absorbed poisons by the various emunctories of the body is always indicated. Here elimination by catharsis and diaphoresis, preferably brought about by hydriatic measures has a useful place. To attempt elimination by forced diuresis is, however, dangerous, as the toxins that are forced through the kidneys are bound to irritate them, and injury to the kidneys should of all things be avoided.

The last and the most important task is to attempt to restore the function of the destroyed hepatic cells. Here the same principles must obtain as in the treatment of any organ that has become fatigued. In very mild cases slight stimulation may at once restore normal tone, in more chronic conditions, however, rest is the prime requisite, for when the affected organ is spared nature soon reestablishes functional equilibrium. We follow this plan exclusively in diseases of the stomach by withdrawing food for a while or by reducing the daily ration. We do it in diseases of the nervous system when we give a rest cure. We do it in diseases of the heart when we put the patient on a mild nonirritating diet and an ice bag over the heart. We are beginning to apply the same plan in diseases of the kidneys, and it certainly has a grateful field of application in the case of the liver.

Following a period of rest, what might be termed gentle exercise of the organ may be instituted either by throwing upon the liver tasks that it should normally be able to fulfill or by gently stimulating it with remedies or physical measures that we know can fulfill this purpose. Active stimulation with powerful remedies should be reserved as an emergency measure in extreme cases, for nothing will produce complete functional inadequacy of an organ that is functionally impaired so rapidly as over-stimulation in the beginning.

For the purpose of stimulating the function of the liver we can have recourse in the first place to certain hydrotherapeutic measures. It has

*See Croftan. "The dangers of an exclusive milk diet, etc."—*Medicine.*

been established by careful studies that general hot baths or the short application of cold locally over the liver, preferably in the form of a stream of cold water directed for a minute or two against the hepatic region, will energetically stimulate *the flow of bile*. The same result can be obtained by the application of a so-called Priessnitz compress over the liver region. A towel is wrung out of cold water and laid over the liver and covered with a flannel. Many remedies are said to stimulate *the formation of bile*. Unfortunately, most so-called cholagogues do not possess this power at all, but simply irritate the stomach, the intestine, and the liver. Best of all are the salicylic preparations and the bile acids.* Preference should be given to the latter remedy because the salicylates are undoubtedly irritating to the kidneys. The stimulation *of the glycogenic function* of the liver can be brought about by an active alkali therapy. Antipyrin, too, possesses this power. Best of all, however, are the starchy and sweet foods, and as these are already properly included in the diet, as mentioned above, it really seems unnecessary to give any medicine for this particular purpose.

We know of no remedy that can stimulate *the urea-forming function* of the liver. The administration of abundant albuminous food constitutes a physiological stimulant to this function, and, if sufficient care is exercised that the bowel is kept aseptic, there is no reason why plenty of albumen should not be given for this purpose, especially in mild stages of the disease. Some writers have advised the use of urea, itself, claiming that a certain amount of urea is necessary, especially in order to promote diuresis, and that where its formation is deficient it should be supplied. This plan does not appeal to me, and, despite the various favorable reports on this therapy I have never been able to convince myself of its value.

In conclusion, a word in regard to the use of *liver extracts* in this disease. A number of French authors, chief among them Gilbert and Carnot, have published very enthusiastic reports in regard to the amelioration following the use of powdered calf's liver or pork liver given suspended in milk or water by enemata or even subcutaneously. Symptomatically I have seen some good results from the ingestion of liver extract in cases of cirrhosis of the liver with hepatic insufficiency, especially in the direction of an increased urea excretion, an increased tolerance for carbohydrates, and an apparent improvement in some of the nervous manifestations. That the administration of liver extract stimulates the regeneration of liver cells, that is, produce a vicarious hypertrophy of those portions of the liver that are not affected, is hard to prove.

Finally, something may be said in regard to the *danger of operative interference* in cases of hepatic insufficiency. There is in most of these cases a tendency to hemorrhage due, possibly, to the circulation in excess of bile acids; for the latter have a distinct hemolytic power and interfere with the coagulability of the blood. Besides, the administration of chloroform is a very dangerous procedure in any case, even of mild hepatic insufficiency, for, in predisposed subjects who, we must assume, possess an idiosyncrasy against chloroform, a condition may develop which closely simulates acute yellow atrophy of the liver, both chemically and anatomically.† I think it is just as important for this reason that surgeons should, as far as possible, examine the functional state of the liver before an operation as they do, or should, study the condition of the kidneys. If any of the evidences of hepatic insufficiency that have been enumerated above should be present, then chloroform at all events should not be administered as an anesthetic and the possibility of profuse capillary hemorrhage be remembered. If it were not for this difficulty of operating upon cases of hepatic insufficiency the so-called Talma operation might prove of value, relieving the liver of much work and aiding it to regain its normal powers.

THE OFFICE TREATMENT OF ANAL FISSURE.*

By SAMUEL G. GANT, M.D., L.L.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE RECTUM AND ANUS IN THE NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Anal fissure is a common, persistent and most distressing affliction and is very frequently improperly diagnosed and treated. Fissure in ano may be defined as an elongated rent, or ulcer of the anal mucosa at its juncture with the skin, characterized by tearing, or dull, radiating pain and prolonged contraction of the anal sphincter. True fissure is invariably accompanied by severe and frequent sphincteralgia and must not be confused with superficial cracks in the skin or mucosa unaccompanied by sphincteric spasm. Fissure in ano is one of the most frequent of all affections encountered about the anus in the well to do; occurs more frequently in men than in women; and may be met with in both adults and children. These lesions are parallel with the long axis of the gut, are nearly always single, are usually located at the posterior anal commissure, vary from one to three-fourths of an inch in length and may extend partially or completely through the mucosa. In the latter case, the sphincter muscle can be seen crossing the rent at a right angle.

There are two types of fissure in ano from an etiologic standpoint. The first type is caused by injuries, such as tearing of the mucosa by foreign bodies or the passage of scybala, or the rent or ulcer may be the remains of an improperly treated sore or wound, or the result of over stretching of the anus with the fingers, anal dilators, or other mechanical instruments devised for divulsing the sphincter. The second type, first described by Ball, is produced by the detachment of a semilunar valve. Subsequent passages extend the injury, since each action causes the torn piece of mucosa and valve to be dragged further downward, separating it from the musculature beneath, in a manner similar in many respects to the formation of a hang nail on the finger. Eventually the rent extends to the skin and the mucosa becomes edematous and the skin inflamed and swollen, forming the typical sentinel pile, in the center of which is to be found the fissure (Fig. 1), the rent being easily exposed by separating the margins of the anus. With the exception of this so-called sentinel pile, the characteristics of both types of fissure are the same.

Symptoms and Characteristics.—In a recent fissure the edges are clear cut, it is not sensitive, bleeds frequently, there is slight, if any sphincteralgia and but little pain, which is of a tearing or burning character and subsides shortly after defecation. Chronic

*Read before the South Essex District Medical Society, Lynn, Mass., February 20, 1906.

or true fissure presents quite another picture, the anus is tight and drawn upward, efforts to examine the rent cause spasm of the sphincter and sharp pain and when it is exposed the ulcer will be found to be exceedingly sensitive and the edges inflamed, thickened and rounded. In neglected cases, the patient experiences sharp, tearing or burning pain at the anus during, and for a short time following stool. The stretching of the fissure during defecation starts up intermittent, spasmodic contractions of the muscle, which induce very sharp pains. In a short time the contraction becomes almost, if not tonic, and the patient forthwith begins to suffer from continuous, dull, agonizing pain in the sacrococcygeal region which may subside in a short time or last for many hours. These pains and the sphincteric spasm are the pathognomonic symptoms of fissure in ano. Patients suffering from fissure often complain of vesical and urinary complications because of the reflected pain and the excitation to spasmodic contraction of the muscles of the rectovesical region. Hemorrhage is never dangerous in fissure cases, the bleeding begins during defecation and the blood may be noticed as a streak upon the feces or in larger amounts on the toilet paper. The discharge

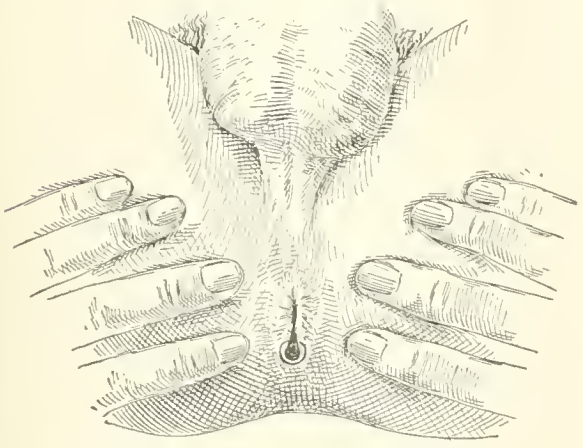

Fig. 1.—Showing fissure and sentinel pile.

from a painful ulcer or fissure is not abundant, but is sufficient to keep the mucosa and skin about the anus constantly irritated, causing a persistent and annoying pruritis. Constipation is always a symptom of fissure, due largely to the fact that defecation causes great suffering and the patient defers going to stool as long as possible. Persons suffering from this complaint are usually extremely nervous and not infrequently melancholic owing to the great pain, loss of sleep and, in many cases, to the difficulty experienced in obtaining permanent relief.

Diagnosis.—Fissure in ano is often mistaken for other anal affections and vice versa; this is unnecessary, however, and rarely occurs in the practice of surgeons who have a routine method of examining the anal canal. In suspected cases, the fissure can be brought into view by carefully separating the margins of the anus (Fig. 1), and, in women, this can be accomplished by inserting the finger into the vagina and everting the anus. If no rent can be located in the above manner, the patient has no fissure and a digital and proctoscopic examination of the rectum should be made to determine the nature of the trouble.

Treatment.—The writer knows of no other ailment more often improperly treated than fissure. A patient is not infrequently tortured for weeks or months by cauterization, divulsion or topical applications by some ignorant practitioner, when the lesion should have been speedily and almost painlessly healed, had it been properly handled. The treatment of fissure is simple, requires but a short time, causes but little suffering and is universally successful when carried out by some one who is capable and bold enough to resort to radical methods, even though the patient pleads for some seemingly less severe procedure. A fissure of recent origin unaccompanied by sphincteralgia can be cured in most instances without recourse to surgical interference. The patient should be placed on a light diet and instructed to take a laxative in order to secure each day one or two semi-solid evacuations. It is not necessary to stop work, but violent and prolonged exercise should be discouraged. The fissure should be wiped out after each stool; this can be effectively done by twisting a piece of cotton on the end of a wooden toothpick and dipping it in some antiseptic solution; the medicated cotton is then pushed up the rectum for about one inch and withdrawn through the fissure. This procedure causes but slight pain and rarely requires to be repeated. After it has been thoroughly cleansed, topical applications of silver nitrate, 10 per cent., ichthyol and glycerin 15 per cent., or balsam of Peru, should be made by means of the toothpick applicator, or citrate of silver or calomel ointment may be applied twice daily. Good results are sometimes to be had from dusting the surface of the fissure with orthoform, or calomel. As a rule, however, the writer prefers the use of liquids to powders, for the reason that the latter sometimes cake, and cause an annoying pruritis and pain. The applications should be continued until the ulcer has been completely healed and the patient should be warned against allowing the stools to become hardened, until the cicatrices have been firmly formed.

As a general rule a chronic fissure or one which is accompanied by sphincteralgia requires surgical interference in order to effect a permanent cure. Some patients suffering from the affection refuse to have an operation performed at all and others until after non-surgical measures have been tried and failed. In such cases the diet should be regulated, a laxative should be prescribed and the fissure cleansed in the manner already described. In the true, or deep fissure, drainage is not so good as in the superficial variety because of the depth of the rent and the contraction of the sphincter. For this reason it is essential that the topical applications should be made upon gauze and allowed to remain *in situ* until the patient has an action, since the gauze will absorb the discharge. The favorite remedies of the writer to be applied by means of gauze in the treatment of true fissure, are nitrate of silver 20 per cent., ichthyol 50 per cent., and balsam of Peru full strength. These stronger agents are used for the first few applications only, and are followed by the milder solutions and ointments referred to in the treatment of superficial fissures. The pain caused by topical applications can be minimized by aplying a 10 per cent. solution of eucaine or cocaine before they are used. Caustics, such as stick silver, copper sulphate and like agents, should not be used in these cases, because they induce the most intense pain and sphincteralgia which may continue for hours after the application. When cauterization is resorted to it should be done by means of the galvanocautery after the fissure has been anesthetized by the injection into its base of a sufficient quantity of sterile water, or weak solution of eucaine. It can then be thoroughly burnt without causing any suffering.

Surgical Treatment.—uSrgical procedure should be employed whenever possible, because it is the quickest and most satisfactory method of treatment, for the reasons that a cure can always be effected, and with a minimum amount of suffering. Under the old regime, patients often refused surgical interference in these cases, and justly so, because it was the custom of surgeons generally, to send these sufferers to the hospital, require them to take a general anesthetic, and remain in bed from one to three weeks. This practice of giving ether or chloroform to this class of patients and detaining them in the hospital for a considerable length of time is unnecessary and should be strongly condemned, because a radical cure can be effected in the office or at the home of the patient, by means of a local anesthetic, thereby avoiding the danger of general anesthesia and long delay from business or social duties. It has been the custom of the writer for a number of years to operate upon all fissures by means of local anesthesia. He has demonstrated in hundreds of cases that the various surgical procedures suggested for the relief of this ailment, viz.: incising the sphincter, divulsion and excision of the fissure, can be successfully, quickly, and painlessly done by means of local anesthetics.

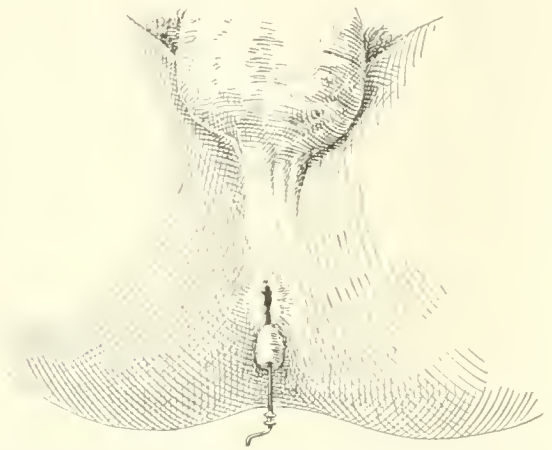

FIG. 2.—Showing swelling and blanching of the tissues caused by the solution, and also needle and Gant curved extension piece used in making the injection.

Incision.—It has been conceded by proctologists for a great many years that a fissure does not heal, because the wound seldom remains quiescent on account of the spasm of the sphincter beneath it. To overcome the undue activity of the muscle, the operation of divulsion was devised with the object of sufficiently stretching the sphincter to induce temporary inactivity at the anus and thereby give the wound an opportunity to heal. While this procedure was a great step in advance over the older methods of treatment, it has not proven entirely satisfactory and will, in the writer's opinion, soon give way entirely to the incision operation. Many cases can unquestionably be cured by means of divulsion and topical applications, but on the contrary, many others will not be so fortunate, because the muscle regains its activity before the wound has healed. Incision or division of the sphincter is unquestionably the operation of choice. When properly performed and the after treatment carefully carried out, a permanent cure will be quickly and almost painlessly effected in every case. Some operators advise a partial division of the external sphincter, but in the experience of the writer it has not been satisfactory, because it is extremely difficult, owing to the thinness of the muscle, to limit the cut and further because when it is only partially severed it does not always insure the desired rest that invariably follows the complete operation. The old operation consists in administering a general anesthetic, inserting a sharp pointed curved bistoury into the rectum, when it is withdrawn, severing the external sphincter. This operation should be discarded for the reasons that a general anesthetic is given and further, because a cure is not infrequently delayed for weeks owing to the difficulty in keeping the cupshaped incision properly drained. The writer has devised a simple operation for the permanent cure of fissure which is invariably successful and which can be performed in five minutes, the only anesthetic required being sterile water or a one-eighth of one per cent. eucaine or cocaine solution. This operation has been performed by him three hundred times without serious accident or complication and in not a single instance has it been followed by unpleasant sequelæ. A cure has been effected in every case and the post-operative pain has been much less than that following the older method. As will be seen in the description of the technic of this procedure, the success of the operation is due entirely to the nature and extent of the cut through the muscle and adjoining structures, which insures complete inactivity of the sphincter, permits perfect drainage of the wound, and the insertion of dressings with but little if any pain.

Technique of the Gant Operation.—The patient, previously prepared, is placed upon a low table in the lithotomy position, or upon his left side with his legs flexed upon the abdomen. The buttocks are held apart by an assistant; the operator then seizes a fold of skin in the median line one inch from and posterior to the anal margin and compresses it between the thumb and forefinger to lessen the pain caused by the puncture. A syringe holding not less than one ounce, filled with sterile water or fitted with a Gant curved extension piece and sharp needle, is filled with sterile water or, preferably, one-eighth of one per cent. eucaine solution. The needle is introduced between the layers of the skin and a sufficient amount of the solution is injected to produce a whitish swelling, which indicates anesthesia at that point. The needle is then inserted further and further until anemia of the skin from the point of entrance up to the anal margin has been produced. It is then directed inward and a sufficient amount of the solution deposited to form a firm, round, whitish tumor about the size of a pigeon egg. The external sphincter and posterior rectal wall for a distance of one and a half inches are now injected and anesthetized in a similar manner, when the operation can be proceeded with painlessly. In producing local anesthesia by this method, it is not necessary to waste time in endeavoring to locate any particular nerve branches, because absolute anesthesia is immediately obtained where a sufficient amount of the solution has been deposited to produce edema, or anemia of the part to be incised. The only instrument used in this operation is a strong pair of scissors having fairly long blades, one of which is sharp and the other probe pointed. The sharp pointed blade is pushed through the skin in the median line, one inch posterior to the anus; at the same time the probe pointed blade is inserted through the anal orifice; the scissors are now pushed upwards for a distance varying from one and a half to two inches, when with one bold cut all the tissues between the blades are severed, making a triangular wound in the posterior median line, two inches in length and one-half inch in depth, which includes the skin, subcutaneous structures,

sphincter muscle, posterior bowel wall and adjacent tissues behind it. Skin tags or piles are now excised and the wound is lightly packed to prevent bleeding; it is then covered by a gauze pad kept in place by means of a well adjusted T-binder. The post-operative treatment following this procedure is most simple and consists in cleansing the wound daily after each stool and inserting a piece of gauze loosely in the cut as a drain and to keep the edges apart. After the first week the gauze is moistened with ichthyol or balsam of Peru to stimulate and increase the healing process. These patients are not confined to their rooms, they are permitted to eat whatever they choose and are advised to secure at least one semisolid action daily in order that the feces may not become hardened and injure the wound then expelled.

Some of the advantages claimed for the Gant operation are as follows: (1) It relieves contraction of the sphincter and sphincteralgia immediately. (2) It effects a cure in every case. (3) It can be performed in from three to five minutes. (4) No general anesthetic is required. (5) It obviates necessity of confinement in a hospital. (6) It is not dangerous or followed by unpleasant sequelæ.

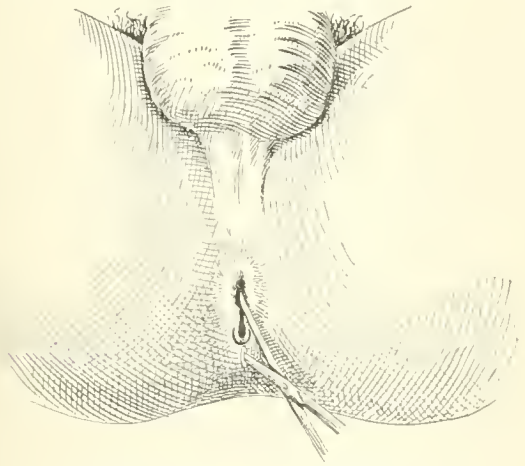

Fig. 3.—Showing scissors in position for dividing the sphincter and adjacent structures in the Gant operation.

(7) The only instruments required are a syringe and pair of scissors. (8) It permits perfect drainage, obviating danger of abscess and fistula, and delay in healing. (9) Owing to the nature of the wound, after dressings can be quickly and almost, if not quite painlessly inserted. (10) It is so simple that it appeals to the common sense of patients who readily submit to it, many of whom would have declined the older method with its many disadvantages.

Divulsion.—Is usually done under general anesthesia, but the writer regards this as unnecessary, since a satisfactory anesthesia can be quickly produced in the office, which permits a thorough stretching of the muscle. The technic in anesthetizing the sphincter is the same as for the incision operation, except that the solution is injected into the muscle and adjacent tissues both at the posterior commissure and sides of the anus. When this has been properly done, the sphincter can be quickly and thoroughly divulsed. The stretching should always be done with the fingers or thumbs and not with large specula, dilators, or other mechanical devices, having no sense of touch and which are apt to do serious injury to the parts before one is aware of it. This procedure has been discarded by the writer in favor of incision operation, for the reasons given above.

Excision.—This operation consists in freshening the edges of the fissure and bringing them together by the aid of catgut sutures, either with or without division of the muscle. Few surgeons resort to this method of treatment, however, because it is more difficult than divulsion or incision and is more dangerous than either, owing to the possibility of infecton.

In concluding his remarks upon the subject of the treatment of fissure in ano, the writer would emphasize the fact that we now have at our command a simple operation for the permanent cure of fissure, which can be quickly, effectively, painlessly and safely performed in the office, or at the patient's home, by means of local anesthesia, thereby obviating the necessity for a general anesthetic and confinement of the patient in a hospital.

43 West Fifty-second Street.

A COMMON FORM OF INSANITY.*

By C. A. DREW, M.D.,

Bridgewater, Mass

Medical Director Massachusetts State Asylum for Insane Criminals.

During the year ending September 30, 1904, 2,426 persons were admitted as patients to the public hospitals for insane in Massachusetts, and to the McLean Hospital at Waverley, who had never before been committed as insane to any hospital. Of these 2,426 cases, 454 (18.7 per cent.) were classified as dementia præcox; 321 (13.1 per cent.) as senile insanity; 276 (11 per cent.) as alcoholic insanity; 257 (10.5 per cent.) as maniac-depressive insanity; 227 (9.6 per cent.) as paresis, or general paralysis of the insane; 133 (5.4 per cent.) as mental deficiency, or imbecility; 91 (3.3 per cent.) as epileptic insanity, and 86 (3.1 per cent.) as organic brain disease.

Each of these types might be called a common form of insanity. But it has seemed best to use the most common type as the subject proper for my paper, some other types being introduced principally for comparison. If it were my purpose to take up type after type of insanity in an effort to help the young graduate to a clearer understanding of the many phases of mental alienation, I could not do better than to begin with that type which he is most likely to meet in general practice. If it happens that the most common form of insanity is that form to which young manhood and young womanhood is most predisposed, this might be an added reasons why we should be keenly alert to recognize the danger signals, and thoroughly posted as to the natural course and probable prognosis of a type of insanity which is preeminently the insanity of youth and adolescence and which is probably responsible for more chronic mental cripples than any three other forms of insanity combined.

As you may infer from this introduction, I have in mind that type of insanity variously known as "pubescent insanity," or "adolescent insanity," or "precocious dementia," or "primary dementia," or "dementia præcox." These terms are generally used in medical literature in a nearly synonymous sense. One author will object to the name pubescent or adolescent insanity because he insists that it is absurd to call a clinical form of mental disease pubescent or adolescent when the patient may be thirty-five years old or older when his mental derangement is first clearly manifest. Others say it is not fitting to apply the term dementia to a

*Read before the Brockton Medical Society, December 4, 1905.

case of mental derangement which may prove curable and in which the most prominent symptoms are hallucinations and delusions, even if the delusions are not of a fixed or systematized type. We must admit the validity of these criticisms. It is true that the outset of precocious dementia is occasionally delayed till the individual is well past thirty. It is also true that there may be times when he does not seem demented at all, even though there be no question about his insanity. Indeed, it is not always easy for those most familiar with mental cases to decide at the first examination whether a patient is suffering from the beginning of a dementing psychosis with a bad prognosis or a mild type of so-called "mania" which we now think of as the exalted phase of "maniac-depressive insanity," in which the prognosis is among the most favorable of all forms of mental disease. Admitting the validity of the objections that may be urged against any of the names in common use, we still recognize the fact that puberity marks the beginning of a decade full of peril to the mental health of any young man or woman handicapped by a strongly neurotic, psycopathic, or intemperate heredity. We must admit also that a large majority of the cases classified as adolescent insanity or primary dementia or dementia præcox do occur during that evolutionary period when the sex organs are ripening and learning, as it were, to functionate, and the reproductive instinct is steadily working that subtle transformation of boyhood and girlhood into manhood and womanhood.

In the study of brain physiology and mental pathology we recognize three epochs that bear an important relation to insanity. These are the periods of puberty and adolescence, the climacteric, more important for women,—and that involutionary period which follows the beginning of senile changes in the brain. We have noted that dementia præcox, —the dementia of adolescence, is, in Massachusetts, the most common of all types of insanity, and that senile insanity ranks next in numbers admitted to our hospitals for the insane. Nomenclature will vary widely according as we follow English, French, or German classification. Indeed, it will vary somewhat widely according to the individual teacher we recognize as most worthy to be followed. But, fortunately, the question of classification is of minor importance. Some well-informed physicians think we had better not attempt divisions and subdivisions of types, which must be more or less artificial. Truly many clinical forms do overlap and verge one into another. The important questions are: Is the individual insane? What is the treatment and what is the prognosis? If it will help the physicians to make a prognosis, or if it makes a difference in his plan of treatment, then, surely, classification is worth while. If we tell the anxious family of a husband and father manifesting the early symptoms of paresis that a few weeks of rest, with a bitter tonic or a trip abroad, will put him right again, we wrong the family and we injure our profession. If we are privileged to watch the case for the next three years, we will learn something about paresis, but the lesson will bring humiliation unless we are very thick skinned. On the other hand, if we hold in mind the hopeless prognosis in general paralysis of the insane, and forget that there is a fairly hopeful type of alcoholic insanity which very closely simulates paresis, then we may suffer loss of prestige because a patient recovers whom we had thought and perhaps declared could not get well.

And so it is in the insanities of adolescence. We learn from the statistics compiled by the State Board of Insanity that 454 cases of dementia præcox were admitted to the hospitals of Massachusetts for the first time during the year ending September 30, 1904. During this period there were sixteen recoveries from this same class of patients. Sixteen is but 3.5 per cent. of 454. Surely we must conclude that the prognosis in this type of adolescent insanity is not very hopeful. But we learn further that fifty-seven cases were discharged much improved and we may fairly expect that some of these have gone on to full recovery at home. If we add the fifty-seven cases much improved, whom we may consider so nearly well as to be capable of self-support, we have a percentage of sixteen capable of self-support from this class of admissions. If we study the question of relapses, we find there were 167 cases of dementia præcox admitted to these same hospitals in Massachusetts during the same year not included in our first count because they had been insane before. Looking a little further, we find ten cases of this class were discharged recovered and nine more much improved. Ten is about six per cent. of 167. Therefore it would seem that the relapsed cases are nearly twice as likely to recover as the cases never before insane. On the face of it, this seems paradoxical, but the key to the seeming paradox may be found in this proposition. The natural course of precocious dementia is a slowly progressive mental weakening without much emotional disturbance or excitement but with foolish and disgusting conduct and absurd ideas about himself and others. Nearly half of these cases improve more or less under favorable conditions to remain mental cripples for life. In a smaller number of cases there is more excitement and less palsy of brain function. Here the symptoms approach the manic-depressive syndrome with a tendency to recover and a tendency to relapse. Here we find an apparent overlapping of two disease forms. Here precocious dementia is impregnated, as it were, with the tendencies of manic-depressive insanity. And so the apparent paradox is reduced to this: Even as one attack of insanity predisposes to another attack, so one recovery points to nutritive and vasomotor disturbances as underlying causes rather than to incurable degeneration of brain tissue. This may sufficiently explain why the percentage of recoveries in relapsed cases of dementia præcox seems to be nearly twice as great as in those cases never before admitted to any hospital for the insane.

If it were true that pubescent and adolescent insanity always means precocious dementia, then the outlook would be dark indeed for any young man or woman attacked by insanity between fifteen and thirty years of age. But, fortunately, such is not the case. A careful survey of the question, we think, justifies this conclusion. Precocious dementia, or dementia præcox, if you prefer the Latin form, is the most common and the most characteristic type of the adolescent insanities. But it may be necessary to differentiate between a whole class of hopeful insanities, due to bacterial and autotoxic agents, to which youth, as well as adult manhood and womanhood is exposed. We have now in mind what is known as the toxic insanities. And the toxic insanities, as Dercum and others have pointed out, are marked above all other insanities by the symptom-complex of delirium, confusion, and stupor. The onset of the toxic insanities are acute as compared with precocious dementia and the element of heredity may be absent or not important. Delirium or confusion or stupor may form the background of the clinical picture and dominate the whole, but

this fact should be kept in mind—that they are closely related states and that delirium comes first in the regular order with mental confusion and stupor as later phases of the toxic type of insanity. Not so many years ago—before we learned the value of the internal and external use of cold water in typhoid fever—toxic insanity, marked by delirium, confusion, and stupor was a very common attendant on that disease. Toxic insanity, however, is not always marked by fever. We make this brief digression to another more hopeful, clinical picture in the interest of a differential diagnosis.

To return again to precocious dementia—New England alienists are now generally pleased to follow the German school of psychiatry which recognizes three clinical forms of precocious dementia, viz., the hebephrenic and the katatonic types, corresponding to the hebephrenia and katatonia of Kahlbaum, and the paranoid type corresponding to the dementia paranoides of Kraepelin.

In the simple dementia of old age, marked mental depression is not common, while an exalted state is very rare indeed. In the dementia of adolescence, moderate depression is a common early symptom, while exaltation and excitement are very frequent symptoms as the case develops.

The younger cases are more apt to follow the hebephrenic course. These are they who seem most demented, manifest least emotional disturbance, and are least likely to be dominated by delusions. Cases somewhat older are more likely to follow the katatonic course. Sometimes silent and depressed, sometimes exalted, loquacious, and incoherent, these cases during the silent periods may sit with rigid muscles resisting passively all efforts to move them, or stand for hours in any place or position in which they may be placed. During the exalted, loquacious periods they may be very entertaining, because of the grotesque delusions of which they talk freely in an amusing way.

The oldest cases are more likely to follow the paranoid course. These are they who are angry, suspicious, and dangerous, because of hallucinations of hearing and sometimes of sight. Their delusions are more apt to be of persecution. A paranoid condition is often used to describe them. They differ from the true paranoiac—the old time monomaniac—in that they have a variety of delusions, which change as the mental degeneration rapidly progresses to a degree of dementia, which is not likely to be reached for many years by the true paranoiac. But in passing to another phase of our subject, I would repeat by way of emphasis, that precocious dementia is almost always an incomplete dementia. Especially is this true of the paranoid type which resembles most true paranoia—the so-called "reasoning insanity."

The very manifest absence of intelligence in the hebephrenic type of precocious dementia, and the grotesque motions, grimaces, and manners with occasional kataleptoid motor symptoms in the katatonic form mark fairly well these two types. The limit of this paper will not admit the report of cases to illustrate the paranoid type.

In five years, according to Dr. T. S. Clouston, 1,800 patients were admitted to the Royal Asylum in Edinburgh, Scotland. Of these, 320, about 18 per cent., were between the age of fourteen and twenty-five Ninety of these, about one-third, had been mentally defective or epileptic from birth, leaving 230, about 12.5 per cent., of all the admissions during that period—in whom it was possible for puberty or adolescence to cause or influence the disease. It is interesting to note that of these 230 cases only one occurred during the fourteenth year and one during the fifteenth year of life. Ten occurred at the age of sixteen and twelve at the age of seventeen. The next three years, the eighteenth, nineteenth, and twentieth, only produced an average of sixteen each year, "while from the twenty-first to the twenty-fifth year the vast majority of cases occurred, viz., 157 of the 230, or an average of thirty-one each year—as compared with an average of eight for each of the first five years of the pubic-adolescent period." Therefore it seems to be true, as Dr. Clouston states, "at fourteen and fifteen the liability to insanity is practically *nil,* and from twenty-one to twenty-five it is very great." This harmonizes well with our own experience.

If this paper should discourage the painstaking treatment of any case of adolescent insanity, it were better had it not been written. If the impression has been made that adolescent insanity is almost hopeless, then the impression is altogether wrong. The truth is that if we exclude iodocy, imbecility and the dementias of epilepsy and infantile paralysis—the insanities occurring between the ages of fourteen and twenty-five are very hopeful.

Recoveries from toxic insanity and manic-depressive insanity in the young range from fifty to seventy-five per cent. as reported by different authorities, although relapses are very common in the latter form.

In regard to treatment, the only safe rule is to consider every case a toxic case or due to some derangement of the physiological functions of the body. "Reflex irritation" has been overworked by certain specialists, each of whom claimed to be able to cure insanity by treating those organs which come within his sphere of influence. But because of the exaggerated claims of some we should not ignore the grain of truth. It is a fact that the central neurons of the neuropath and psychopath are excedingly sensitive to every peripheral stimulus, whether from the eyes, the reproductive organs, or the great internal viscera whose unconscious contributions make up so large a part of organic life Hence it is that to treat insanity most successfully means first of all to treat most skilfully every physical part of the human organism. But there are abnormal mental states seemingly due primarily to morbid thoughts—to worry or prolonged excitement over fancied or really distressing conditions. Here the central neurons suffer first and most, while the abnormalities of peripheral organs may be merely important or unimportant concomitants.

If we can win the full confidence of our patient, the battle for recovery is half won—then will the harassed brain throw off a large part of its load. A brisk purge may be the best of all medicines at first. Every organ whose function is to eliminate must be made to do its best, not forgetting the importance of the skin. If any organ is crippled so it cannot eliminate, then other organs must do double duty. Home environments are often the greatest obstacles. The adolescent who is idle, apathetic, irritable, resistive, and threatening at home commonly falls into line at once among strangers in the routine of a well-ordered hospital.

Next in importance to elimination is oxidation. An excess of outdoor exercise must be insisted on. As well let a freezing man sit still and doze under the stars of a winter's night as to let a morbid adolescent sit and brood over his "lost manhood" or

the coquettish girl who has jilted him for another youth. A robust nurse of good sense and strong will is essential for successful home treatment. For an excited or resistful patient two such nurses are necessary. Hydrotherapeutics and massage are important means to curative ends. Electrotherapeutics is sometimes of value, largely, in my opinion, through its effect on the imagination. Details of treatment, which will vary with each patient, should be left to the individuality of the physician. In regard to food and drink, I should say avoid alcoholic stimulants and advise a generous but non-stimulating diet. Avoid the bromides, hyocine, chloral, opiates, and all narcotic drugs if it is possible. A warm bath or wet pack, with a glass of hot milk and a brisk rub, is a good hypnotic. All hypnotic drugs, in my opinion, are bad, but may be the least of evils in the presence of unbearable pain or continuous excitement when nurses and family are worn out with long watching.

THE PRACTICAL MANAGEMENT OF TYPHOID FEVER.*

By CHARLES E. NAMMACK, M.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE HOSPITAL; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

GENTLEMEN: I will omit the customary introductory rhetorical apology for the triteness of the subject of this paper. The subject was your choice, and no apology is necessary, for typhoid fever, like the poor, is always with us, and general practitioners, like the members of the Bronx Society, are more interested in its practical management than in the morphological distinctions which may obtain between the various bacilli which may be extracted from the typhoid intestine for painstaking cultivation in a laboratory. Valuable as the laboratory study of this disease during the past ten years has been, there is some truth in the shrewd intimation of a recent writer that if the same time were spent in studying the patient which is now spent in studying his blood and his secretions and excretions, we might be able to save some of the 50,000 lives lost in this country every year, to say nothing of the 250,000 who recover with systems racked by the disease. If from 1821 to 1859 the mortality in the Massachusetts General Hospital was 12.75 per cent., while from 1859 to 1899 it was 15.5 per cent.,[1] it cannot be said that we are managing this disease any better than were our predecessors, who were ignorant of the bacillus of Eberth, and of the Widal reaction, and of the advantages of a differential leucocyte count. Lest I be misunderstood, however, let me distinctly disavow any intention to underrate the beneficent results of this laboratory knowledge. If Pittsburg can afford to allow her drinking water to remain loaded with typhoid bacilli that her citizens may furnish a death rate of from 124 to 144 per 100,000, while Dresden, in Germany, a city of about the same size, is anxious to remove the bacilli and reduce the death rate to 4 per 100,000,[2] that demonstration alone justifies all the time and study given to the bacillus. It is only my purpose to deplore the fact that, although prophylaxis has made mighty strides by help of the biological knowledge of the disease, treatment of the developed cases has not kept pace with prevention.

What is the reason for this? Are we doing too much, or too little? Or are we doing the wrong things? One of the first things expected from us in private practice is a prescription at the first visit. My personal practice is to write one calling for calomel and soda in a fair-sized dose, to be followed by a saline in six hours if necessary. I prefer one good dose of calomel to the repeated administration of fractional doses, especially for children. My next duty is to write out directions regarding diet, treatment of the discharges, and the bed linen. Everything should be done for the patient, and not by him. A bedpan is the first thing to buy. The two essential aims in the treatment of typhoid fever are to feed the patient and to starve the disease. By feeding the patient is not meant stuffing him, and if the relatives can be convinced that manslaughter is not premeditated by me, I would prefer to give the patient nothing but plenty of water for the first few days. The water may be cold or warm, flavored or unflavored, colored or acidulated. Patients like to have an irrigating bottle with tube and shut-off near the bed, from which they can help themselves when the constant attendance of a nurse is not procurable. Emptying the bowels thoroughly at the outset seems to me to furnish the best condition for arresting the growth of the bacillus, although I am quite well aware that anything like intestinal disinfection during the progress of this disease is a hopeless task. The symptomatic treatment of typhoid by intestinal antisepsis excited a great deal of interest ten years ago, owing to the sturdy claims of the late Dr. Woodbridge. This treatment was tried by me at that time in the wards of Bellevue and the Gouverneur Hospitals[3] without beneficial results. Similar measures have since been advocated by others, especially recently by William Ewart,[4] who uses liquid paraffin as a nonirritating mechanical laxative both for lubrication and for cleansing ,with vegetable charcoal to absorb the toxins, and castor oil daily to secure at least one action of the bowels. Ewart is particular to state, however, that sound principles rather than therapeutic formulæ should guide each case.

After the bowels have been thoroughly moved I direct the use of milk, eggs, and water, as the essential foods during the febrile period. Fruit juices and fruit jellies and a daily cup of strained vegetable soup or broth, flavored with beef or bacon, will supply the patient with the necessary mineral salts and satisfy his longing for something besides milk and albumen water. In cases where milk disagrees, or is not digested, whey may be substituted and is preferred by some writers.[4] In other cases, buttermilk, koumiss, or peptonized milk can be taken by patients. Ice cream makes a diverting change. Alcohol may or may not be required, according to the state of the heart and the toxemia. The average case will not need it until later in the disease. Consommé, either hot or frozen, clam juice, oyster soup, thin barley gruels, the commercial malt foods or peptonoids, clarified honey, cream, and the freshly expressed juice of broiled beefsteak furnish agreeable variants. A cup of hot coffee, well diluted with milk, taken early in the morning is unobjectionable. Natural sleep should not be disturbed for food, but where a patient is stuporous he should be thoroughly aroused before food is given, to diminish the danger of inhalation pneumonia. In spite of the fact that solid food is advised by many during the febrile period and that 1,000 cases of mixed and liberal feeding, with a mortality of only 7.7 per cent., have been reported by one observer,[5] my own practice is based upon the conviction that the diet should be liquid, with the additions cited, until the evening temperature has been normal for a week. I believe that the

*Read before the Medical Society of the Borough of the Bronx, February 14, 1906.

measures of diet herein enumerated will provide ample nourishment, will leave the least possible amount of unabsorbed residue to irritate the upper intestine, and will afford abundant variety and support to the patient during the febrile period.

The indications for the use of alcohol are: First, weak heart action as shown by small, feeble, irregular pulse, with feeble cardiac impulse and faint first sound; second, profound toxemia, as shown by delirium, tremor, carphologia, or subsultus tendinum; third, respiratory complications, as bronchitis, bronchopneumonia, croupous pneumonia, or pleurisy; fourth, previous habitual use of alcohol; fifth, persons of feeble constitution and those past middle life. A contraindication to its use is acute nephritis, or chronic nephritis with an acute exacerbation due to the typhoid infection.

In private practice we are expected to order drugs. The most useful prescription, in my opinion, is a combination of hydrochloric acid and liquid pepsin given after the food. To this may be added, when indicated, strychnine. Strychnine will be needed under about the same circumstances as alcohol. But there are some cases in which the typhoid toxins affect the nervous system in a manner similar to strychnine. These cases may be recognized by marked exaggeration of the knee jerk and a tendency to opisthotonus and to trismus. In them, strychnine should not be given.

Ten years ago,[3] I expressed the hope that the serum diagnosis of typhoid fever would soon be followed by successful serum therapy. That hope is yet to be realized. At the present day the most successful agent in the management of typhoid fever is water. The use of water, inside and outside, is not new. Since the publication of Ernest Brand of Stettin, in 1861, advocating systematic cold bathing, the method of tubbing in typhoid fever represents the most marked advance in the management of this disease. The details of this procedure are familiar to you all. Its good effects are by no means limited to the reduction of temperature. In fact, if a case of suspected typhoid fever during the first week shows a drop of more than 2½° F., after a Brand bath, it would be well to revise your diagnosis and look for some other disease. The other beneficial results of the tub bath are shown in the nervous system by lessening of the toxic features; in the circulation by reduction of the pulse and rise of the blood pressure; in the respiratory organs by diminution of the initial bronchitis and passive congestion; in the skin by lessened liability to bedsores; in the kidneys by augmented excretion of urine and of toxins, and in the mortality by a reduction which, when first reported, seemed incredible. It is the only routine measure of treatment for which I leave a standing order in hospital practice. But the labor and expense cannot always be borne by families. It has been estimated that the average cost of each Brand bath in private practice is two and a half dollars, and when a serious case requires several baths in a day for several successive days, the cost might be prohibitive. We are then often obliged to accept a substitute for it. Cold sponging is an excellent alternative and will suffice for a case of moderate severity, but cases with very pronounced nervous symptoms will require the cold pack with sprinkling or rubbing with ice over the pack. Other practical home modifications of the bath treatment may be devised, or will be found described in special treatises, but none of these can fully take the place of the tub bath.

Special symptoms and complications in typhoid fever require the utmost watchfulness on the part of the physician. Headache in the first week is better treated by quietude, darkness, and cold locally, than by coal tar derivatives. Sleeplessness may be persistent and exhausting and demand bromide or chloral. Opium has a bad influence upon digestion and the secretions in the early days of typhoid fever. Somnolence, stupor, and delirium must be treated by stimulants and external antipyretics, and a delirious typhoid patient must not be left alone for an instant. Tremor is an indication for the use of alcohol and strychnine. Dry tongue and sordes will not be prominent if mouth disinfection has been carefully attended to. Vomiting, when occurring early, means either profound infection or extreme gastric irritability. Later in the disease it may be of uremic origin. Constipation, after the first week, should be treated by enemas cautiously given. Diarrhea may require change of diet, especially if much milk be taken, and full doses of bismuth combined with small doses of Dover's powder. If tympanites develop, in spite of the empty bowel treatment which has been advised at the outset, the old-fashioned turpentine stupe, with perhaps turpentine enemas, will be useful. F. F. Caiger, in the Bradshaw lecture for 1904,[6] advises oil of cinnamon (in doses of 2½ to 5 minims, every 2 to 4 hours in gelatin capsules or emulsion) for this unpleasant symptom, as well as for its influence as an intestinal antiseptic and its soporific effect in many patients. A rectal tube may be of service if the gas is in the lower bowel.

For intestinal hemorrhage occurring in typhoid my standing order used to be immobility, ice, and opium. Latterly I have discarded the opium, because it masks the signs of perforation—which is apt to occur in hemorrhagic cases. These signs must be recognized promptly if the patient is to have any chance for his life. Ergotine, hypodermically, or adrenalin, now takes the place of opium, but it is extremely doubtful if any drug of the vasoconstrictor class has any real effect in checking intestinal hemorrhage. Collapse is best met with the subcutaneous injection of sterilized salt solution, about a pint being given in from 2 to 4 places. External heat, absolute quiet, absolute deprivation of fluids by the mouth, posture, and hypodermic injections of stimulants will all be required in addition; but we must carefully steer between overstimulation on the one hand and fatal syncope on the other. There is no longer any doubt about the necessity for surgical operation in cases of perforation, nor any wisdom in selecting cases for operation. Every patient should have this chance of rescue from certain death, and the only contraindication to operation is a moribund condition. Early diagnosis and early operation mean the saving of one-third of these cases, and the weight of opinion and experience is now against waiting until the second twelve hours. The symptoms of perforation should be constantly in mind in every case of typhoid, and should be promptly recognized before peritonitis supervenes to cloud the picture and to render surgical help futile. A peculiar change in the facial expression associated with a feeble running pulse and shivering often precedes the development of the characteristic pain. This pain is of sudden severe onset and increasing intensity, localized at first in the right iliac fossa but soon becoming general. Tenderness and rigidity, followed by symptoms of collapse, and later by adbominal distention, make up a suggestive picture, but it is doubtful if there is a single distinctive symptom, although muscular rigidity *newly arisen*, with coincident in-

crease in the pulse rate, may furnish the keynote of diagnosis.

Conditions which may simulate perforation are pleurisy, pneumonia, cholecystitis, perforation or rupture of gallbladder, acute gastrointestinal indigestion, iliac thrombosis, appendicitis, sloughing of a mesenteric gland, peritonitis, renal calculus, distended urinary bladder, rupture of an acute splenic abscess, and abdominal myositis. In cases of doubt it is better to operate, as typhoid patients stand exploratory laparotomy very well. Cases of peritonitis not due to perforation will not be injured by laparotomy. It must never be forgotten that perforation often occurs without the fulminant symptoms supposed to be characteristic.

Besides intestinal perforation, one other spectre stands by the side of every typhoid patient, and that is cardiac asthenia, due to poisoning by the typhoid toxins. The treatment of this condition consists in its prevention by elimination and support during the early stages. Once developed, its immediate outlook is bad, and its remote prognosis very uncertain.

The chest complications of typhoid fever may be overlooked if careful watch of the respirations, as well as of the pulse, is not kept up. In a case attended by a trained nurse, a bedsore should not be accepted either as a symptom or as a complication of typhoid fever. It is neither. It is a blunder. A moderate range of temperature requires no treatment. High temperature does not demand either antipyretic drugs or guaiacol externally Water will control it more easily and safely. The nervous symptoms of typhoid will likewise respond to ice and water much more comfortably than to depressants, hypnotics, or opiates. Cholecystitis occurs in typhoid fever much oftener than it is recognized, and is believed by John H. Musser and others to be the condition existing in many cases of so-called relapse. If its symptoms are very severe and progressive, operation may be necessary. A true relapse, however, is a fresh attack of typhoid fever and must not be confounded with the many other causes of post-typhoid sepsis. Besides cholecystitis, there may be inflammation of the urinary bladder, or of connective tissue, and although all these are due to the typhoid bacillus, they are not typhoid fever. These septic temperatures will not respond to baths as will typhoid temperatures, and here let me repeat the value of this differentiating information. Some of these will soon be made plain by the evidences of thrombosis of vessels. Others probably depend upon a new streptococcal infection coming on after the typhoid infection, and some of this latter group will do best if they are taken out of bed and fed. Bacilluria causing typhoid cystitis is much more manageable since the advent of urotropin—one of the new drugs that has come to stay.

According to Sir William Broadbent, the convalescence from typhoid fever should last at least a year, and in many cases longer. This period is necessary because the heart suffers from the toxins of infectious disease to such an extent that a certain amount of fatty degeneration is almost the rule. And not only the heart, but the muscular coat of the arteries is likewise similarly affected. The influence of typhoid fever in producing permanent circulatory changes was not appreciated in this country until emphasized by W. G. Thayer.[7] Many cases of arteriosclerosis in early life may be traced to a previous typhoid infection. The convalescence of the average patient may be harder to manage than was the febrile period, but the wise physician will issue just as careful orders regarding diet, exercise, and emotional disturbance, and will decline responsibility unless they are followed. In spite of all care, there is a long line of possible medical and surgical complications and sequelæ of typhoid fever, which subsequently may be attributed by the patient to leniency or lack of firmness on the part of the medical adviser.

The limits of this paper preclude any discussion of the prevention of typhoid fever. It seems strange that a disease which, if every man did its duty, would not exist at all, is still allowed to go on, and that the people of the United States pay an annual tribute of ninety million dollars to its existence.[8] The medical profession can strive to remove municipal ignorance by education, and to show corporate greed by exposure, but this unnecessary sacrifice of life and money will go on until the public conscience is thoroughly aroused.

EARLY DIAGNOSIS AND TREATMENT OF PUERPERAL SEPTIC DISEASES.*

By S. MARX, M.D.,

NEW YORK.

It is indeed a sad commentary on the practice of modern midwifery, when your essayist of the evening, from the vast amount of gynecological and obstetrical material chooses as his theme so prosaic a subject as the early diagnosis and treatment of puerperal septic diseases. Yet, even though I could honestly state that these unfortunate complications were on the wane, the subject is one of interest to all those whose duties bring them in contact with the woman to be confined, or one recently so. But far from this, my experience causes me to know that puerperal complications are not only not on the decline, but during the last few years on the increase. My actual incentive, therefore, is to call your attention to certain factors not alone from the prophylactic standpoint, but to those lesions which, from my experience, are curable when treatment is applied not alone early, but, what would be a better expression, timely. I approach the subject not in a captious spirit, but in one of altruism. Do not mistake the position which I take in this matter in which the *"ergo"* is more real than apparent. The issue which I want to present fairly and squarely is enunciated in the following sentence: "All puerperal septic complications are due to an infective area in some part of the genital tract. It can always be located by sight or touch. If attacked early and energetically the disease is readily curable, and will not lead to deeper and

*Read before the Harlem Medical Association, January 3, 1906.

more dangerous complications. In short, early and active interference ought and will cure practically all cases of septic infections." It may seem foolish to you if I add *provided we are dealing with a septic process at all,* and this is another keynote to the situation. But more of this later. In the prophylaxis—and this has a strong bearing on the subject—we have proven from original investigations personally conducted that the uterus is practically a sterile organ. Furthermore, a vast amount of scientific research has proven that the normal parturient woman possesses a vaginal secretion which has a decided inhibitory action upon pathogenic organisms. This secretion is markedly acid —its destructive action depends upon the lactic acid secreting bacillus of Doederlein. This can be determined by touch and sight. Clinically we have a vagina which requires no artificial preparation to enable us to conduct labor scientifically. The third portion of the genital tract, the vulva, is a different proposition in view of the fact that this territory contains bacteria that propagate actively, especially in the presence of air and in an alkaline medium. They are the *Staphylococcus aureus* and *albus* and the colon bacillus. Thus we are dealing with a part which is decidedly septic and infectious as is the ordinary skin, and must be treated as such according to well-known surgical principles. Therefore in the management of an obstetric case from the modern standpoint we have but one area which must bear the brunt of our energies so as to render it sterile. This is the limitation of our preparatory treatment, so far as the normal woman is concerned. No antepartum douches, no vaginal toilet, etc., are permissible. So firm is my confidence in Nature's ability to destroy every possible pathogenic germ that may be introduced by operative or manual interference that, when the asepsis of the operator cannot be questioned, no uterine or vaginal douche is ever allowed either before, during, or after the operation. When from bacteriological experience or clinical demonstration this vaginal inhibitory action does not obtain, we are dealing with a secretion which is alkali, profuse, malodorous, and purulent, consequently pathological and in most cases gonorrheal. Now the indication is prophylaxis, and we anticipate the labor by appropriate treatment, and if, when labor sets in, the discharge is not normal, surgical scrubbings, such as are done prior to major vaginal work, are distinctly called for; and, if the labor be prolonged, vaginal douches are administered at short intervals with the hope of destroying, or at least inhibiting, the action of these pathogenic organisms. In approaching a normal labor we never allow douches of any kind, but as far as lies in our power we render the external genitals sterile. The strictest attention is paid to the hands of the examiner. Since the assertion so forcibly set forth that the healthy parturient vagina is naturally in an aseptic condition, there can be only one source of infection —directly or indirectly—and that from the accoucheur or from without. Autoinfection is so rare that for practical purposes it has hardly a bearing upon the subject. Furthermore, in these healthy women no matter what form of operative treatment has been undertaken, whether the forceps has been applied or a version done, or for any reason the hand has been introduced into the uterus. we have not allowed for many years the tract to be washed out or irrigated for the sole purpose of washing out, or at least of attempting to eliminate or limit the sepsis which under these conditions might have been introduced. An intrauterine douche will wash out blood clots and cause a uterus to contract, but we doubt very much whether such irrigations can, even by any possibility, wash out any but the germs that lie on the surface, and this is problematic. We go still further and state that even in the cases known to be septic no uterine douches after labor can be of any service in eliminating the infection, and under these conditions it has been our custom to attempt to limit this infection, first by causing a firm contraction of the uterus, and secondly, by the use of a remedy that will be readily absorbed, and which, by its antiseptic properties, will destroy the germs that lie in the deeper recesses of the organ. This end is obtained by the firm packing of the uterus with iodoform gauze.

In the puerperium all elevations of temperature, or an abnormally high pulse rate, with or without fever, must be looked upon with suspicion, always viewing the case as one of sepsis until this condition can be absolutely diagnosed to the exclusion of all other extragenital complications. The antiseptic conscience and the aseptic hand cannot alone be sufficient certification that sepsis is not present. A complete and thorough physical examination must always anticipate a local one except in those cases in which unfailing evidence is present that the sepsis is the *one* condition present, and none other. Personal experience has brought me in contact with cases of acute lobar pneumonias in which uteri have been religiously irrigated for days for a supposed puerperal sepsis. Likewise retromammary abscesses, pyelonephroses, and many other conditions were found as the cause of temperatures in the particular cases. Yet in every case, with but few exceptions thus far brought to my notice, the uterus has been constantly and persistently treated, most practitioners looking upon the temperature after labor as septic, and, without rhyme or reason, causing the unoffending uterus to bear the efforts of their endeavors. I may add to this by stating that I hardly remember seeing a case of fever after labor, no matter what the cause of such might have been, in which the uterus had not been curetted or irrigated, or both, whether the indication therefor had been clear or the diagnosis had been clinched. If it is chagrining to the consultant, how mortifying must it be to the attending physician to have the former discover a pneumonia or a mammary abcess present which had been the cause, and had been treated for days by curetting and constant uterine irrigation? To attempt to melt an iceberg by a hand atomizer would be about as successful. There is too much tinkering with the uterus—for I have seen temperatures kept up by senseless uterine irrigation. My conclusions as to these latter words may be summed up epigrammatically as follows: "Don't curette and then hunt for a diagnosis; but diagnose and act accordingly."

In the diagnosis we search locally and generally for the cause. Excluding extragenital lesions which might have a bearing on the condition and a good history of the case, we can readily concentrate our attention upon the source of greatest danger in the puerperium—the vagino-uterine tract. A blood examination should always be made. From such an examination I have repeatedly been in position to diagnose a paludal poisoning by finding plasmodia in the blood; even though the temperatures were atypical, the history negative, and the spleen but slightly enlarged. These cases which are improperly called puerperal malarias, when in reality they are malarias complicating the puerperium, are in my experience more frequent than

we are led to believe. The diagnosis was not made by empiric thoughts nor entirely by quinine therapy, but by the presence of the specific organism. The presence or absence of an increased leucocyte count is of little value to us, for the main reason that immediately after labor there is such a rapid fall of the leucocytes, amounting to almost a third, that we cannot lay too much stress upon this particular symptom. This I have shown elsewhere from a study of this subject during pregnancy and the puerperal state. To what extent the polynuclear count will bear upon the subject I am not prepared to state. The presence of streptococci and staphylococci in the blood is conclusive when found, but how often in just the cases we expect to find them are they not absent? For this reason while when they are present the diagnosis is assured, their absence does not prove that a severe sepsis may not be present. Of the greatest importance is the local examination. This can be complete only when supplemented by a careful visual examination. Unless the symptoms point to an undoubted uterine sapremia, the visual inspection must anticipate the manual examinationn. A large tender uterus with a putrefactive malodorous discharge means a pure sapremia from retained secundines, and nothing else. A small non-tender uterus with sweet discharges absolutely excludes the presence of retention products. This must not be interpreted in too absolute a sense, for there is no recently pregnant uterus that does not contain some of the remains of the products of conception. These do no harm if the accoucheur has been clean and no sepsis be present. Dangerous as it may appear, I want to go on record as believing, and practising as I preach, that where strict asepsis has been secured small placental particles and membranes may be left behind with impunity. The great danger lies in studiously hunting for them immediately postpartum, when if left alone they would be discharged spontaneously with no danger to the patient nor discredit to the physician—providing that the too ambitious consultant or the inquiring medical attendant hunting for a supposed source of infection and *his pound of flesh* brings not to light by his curette a small particle which may be a harmless placental atom or a thin shred of membrane, or, what is more likely, an inoffensive blood clot. Again I say the man who hunts for something in the uterus will always find it, but I question whether, in the absence of sapremia, he does not do more harm than good.

It is to the so-called puerperal ulcers that I wish to call your attention specifically. I have maintained for years that practically all sepsis arising after labor gains its entrance from these lesions, whether they be situated at the vaginal outlet, their most frequent site, or upon or within the cervix. Further timely recognition and treatment will cut short many a case of beginning sepsis that would otherwise lead to a prolonged and dangerous illness, providing the initial lesion had been discovered early. Many cases have come under observation in which a most insignificant puerperal ulcer has had its career cut short and the attendant symptoms of an infection cleared up by attention to this lesion and nothing else. Further experience has taught that when a rapid defervescence of these symptoms, does not occur in short order we are dealing with an accessory extragenital lesion, whether septic or not. Thus the records show at least twelve cases in which such a condition confronted us. An examination of the blood showed plasmodia, which as a concomitant associated condition caused the delayed fall in the fever. Administration of quinine rapidly cured the case. On the other hand, primary examination of the blood presented plasmodia; quinine, while it allayed the chills and irregular temperatures, and caused the disappearance of the plasmodia, still did not cause the temperature to disappear. The discovery of some puerperal ulcers and their treatment gave a complete apyrexia in a few days. Visual inspection is necessary to discover these so-called diphtheritic ulcers. Anedematous condition or pain on pressure over a recently sewed perineum warrants the immediate removal of all sutures, for hidden areas are the most likely and most dangerous sources of infection. A personal classification divides these ulcers into two classes: (1) desquamative and (2) exudative. They may be situated upon any area of the genital tract from the perineum to the endometrium. The desquamative ulcers appear merely as extensive mucous membrane excoriations. The part is dry and angry looking and red and hot. The epithelium is absent and the mucous follicles appear macroscopically as minute pinheads. Radiating red streaks of lymphatic involvement are very evident. These ulcers stand in sharp contrast to the surrounding mucous membrane. If neglected these ulcers soon become covered with a slough or pseudomembrane, and take on the character of the second or exudative ulcers. Here the picture can be likened only to a very light diphtheritic membrane covering, but only slightly adherent to, the underlying tissue. The parts of predeliction to be attacked are in the milder cases the deep crevices and sulci in the perineum, vagina, and lacerated areas upon the cervix. Glands may or may not be enlarged, but often the veins at the bases of the broad ligaments are thrombosed. Around these ulcers the interest of my paper must center. I maintain that practically all cases of puerperal septic infection arise from these ulcers, and their recognition will terminate practically nearly all cases of beginning infection. Even though placental tissue and membrane are retained they will not cause sepsis unless infection be carried to them. Further, that if all cases of genital infection be examined early enough, these ulcers will be found in an overwhelming majority of cases as a distinct entity in the causation In the absence of suspicious evidence of an infection the bacteriological examination of the uterine contents becomes of enormous value if it can be done by one expert in getting such tainted material. But because of this difficulty it becomes a measure eminently not suited to the practitioner in general, but fitted to one expert in this line under conditions in which such a culture cannot be contaminated by extraneous material. My deductions are based upon some forty-seven examinations after labor. The size of these ulcers varies from an area difficult to see to one whose limitation is that of the entire perineum, vagina, and uterus. In these latter cases the entire vaginal tract is completely covered with a diffuse grayish membrane extending as far as one can see into the uterine cavity.

Treatment.—We limit ourselves to the early cases and differentiate uterine from vagino-perineal sepsis wherever the line can be consistently drawn. If visual inspection reveals no lesion of the perineum, vagina, or cervix, we examine further as to the status of the uterus. Foul discharges, high temperatures, and relatively low pulse can only mean intrauterine sapremia. We are then, and then only, justified in exploring for retained products of conception. Having located these as the source

of infection they are removed by any means at our command; whether by the curette or hand is simply a matter of choice, as the experience of the operator teaches. This is done once, and once only—further drainage being secured by intrauterine gauze or drainage tube. But this is all; for if this be the source of infection, and is thoroughly removed, it will positively shut off danger from this direction. If decomposing intranterine secundines are not found, the symptoms of sapremia nevertheless being evident, we are then dealing with a puerperal ulcerative endometritis. This diagnosis is made all the more positive by the presence of ulcerative areas upon the cervix. Here any active intrauterine interference is positively contraindicated. Curettage is the worst possible thing to be done, for you curette away this sloughy area, denuded as it will be, to be attacked by a new slough each time it is thus traumatically bared. You thus carry the infection deeper into the uterine wall and open up fresh areas of infection. Our strength of attack is by no means of pure cauterants. A thorough application of pure carbolic acid, 50 per cent. solution of zinc chloride, or the pure liquor ferri are all at our command. The uterus is thus treated by means of pure alcohol gauze, in the center of which is placed a large drainage tube leading from the uterus into the vagina. Into this tube, and thus keeping the intrauterine gauze moist, are injected from four to five ounces of pure or 50 per cent. alcohol four to five times a day. This gauze can remain in place without changing for a number of days. An ice-bag over the uterus and large doses of ergot complete the treatmennt. It is just in this class of cases that we deprecate overactive treatment. Other things being equal, the less tinkering done the better are the chances for the patient. In a series of thirty-two cases seen in the short period of six weeks, only one patient died, and she was a bad subject from the start. In cases of puerperal ulcers in other parts of the genital tract, it is our purpose to attack them vigorously from the start. The exudative variety is readily recognized, but it is more difficult with the desquamative ulcers. With the latter, careful and close examination, comparing one part of the tract with the other will soon reveal the infective nidus. Where ulcerative areas are evident and limited to the lower genital tract, under no condition is the interior of the uterus to be invaded by hand or instrument for the one evident danger of carrying the infection higher up. The above-mentioned cauterants are most vigorously applied. Carbolic acid in pure form is our choice, because of its painlessness, its deep searching influence, and the wonderful inhibition alcohol plays in the control of its action. The acid is applied to all parts infected, followed by pure alcohol in the course of a minute or so. This is repeated every twenty-four to thirty-six hours until the parts appear healthy. A decided drop in the temperature soon follows this application. A strip of gauze is introduced within the parts to cause a separation of the tissues thus treated, and douches are regularly given. Thus I end my article. Puerperal infection depends upon infection from without, gaining its entrance practically always by lesions in the vagino-uterine route. Discover these, attack them energetically and wisely, as you would infective areas in other parts of the body. Overtreatment is reprehensible, unwarranted treatment dangerous. The curette has served us well in appropriate and selected cases. This instrument should not be blamed for its shortcomings; the blame rests with the man behind it, even as it is the man behind the gun who does the work. The curette is blind; the guiding hand is sentient; thus always, as in life, let the seeing, guiding mind lead the blind. He who seeks blindly seeks not too well.

THE DETERMINATION OF THE ABSENCE OF HYDROCHLORIC ACID BY A SIMPLE STOOL EXAMINATION.

By ALFRED F. HESS, M.D.,

NEW YORK.

Until recently we rarely met with an article relating to the examination of the feces. Of late, it is quite the contrary, and especially during the past year many articles urging the importance of stool examinations have appeared. The cause of this sudden interest in this branch of laboratory work has undoubtedly been the introduction into clinical methods of the Schmidt test-diet.[1] Before such a diet was devised the work was necessarily desultory, as no clear idea of the contents of a normal stool existed and we could not distinguish the physiological from the pathological. It hardly seems requisite to review this comparatively new method, as a full account of its composition and of the different steps of the stool examination and their respective significance has appeared recently in this journal[2] and elsewhere.[3] Moreover, the one point to which I wish to call attention and emphasize, although based upon the test-diet, does not depend upon its application.

Before proceeding I should like to mention that my experience with this line of work began in the summer of 1904, when Prof. Schmidt was kind enough to allow me the use of his wards and laboratory. Since then I have carefully followed the articles bearing upon this subject, but would not have contributed the result of my experience had it not seemed to me that one of the essential points, perhaps the one best suited to practical therapy and the easiest of application, has been almost entirely neglected in the articles which have come to my notice. I have in vain been waiting for the following striking fact to be brought out strongly for the use of the clinician, namely, *that from a naked-eye examination of the finely divided stool it is possible to diagnose the lack of secretion of hydrochloric acid by the stomach.* The fact that connective tissue in such cases can be demonstrated by the microscope has been well brought out.[4]

The method of procedure in order to ascertain the deficiency of hydrochloric acid is simple. The rigid test-diet, as I have mentioned, need not be prescribed, so that all objections to its large quantity of milk are not pertinent. All that is required is that the patient should eat daily for three days prior to the stool examination not more nor less than one-quarter of a pound of chopped beef, *cooked so that it is still rare within.* In addition to the meat there may be allowed oatmeal, soup, eggs, mashed potatoes, jelly, toast, zwiebach, butter, sugar, milk, coffee, tea, cocoa in any form or combination whatsoever—not in unlimited quantities, but in moderate amount. He may eat two eggs a day, twice of oatmeal, and enjoy for dinner the chopped beef and mashed potatoes in addition to the accessories mentioned. Surely this is a sufficiently liberal diet for a sick person for a period of three days.

This regimen having been carried out, we are ready at the end of the third day to examine the stool. This does not consist of the usual cursory glance. The stool should be mixed with a spatula

and then a mass about the size of a walnut should be *thoroughly ground* in a mortar, making gradual additions of water until no solid material is visible. Upon the thoroughness of this process depends the possibility of the diagnosis. The fluid is then poured upon a plate with a black background, and to one of moderate experience the diagnosis is now possible. Often a rapid survey is all that is required.

The physiological and chemical basis of this test is founded upon the established fact that connective tissue can be digested only by the gastric juice. This being the case, it is clear that, provided we know the quantity of connective tissue which a healthy stomach can digest, we can use the presence or absence of connective tissue in the stool as a gauge of the amount of hydrochloric acid secreted by the stomach. This factor has been ascertained. As the result of experimentation Schmidt found that the normal stomach secretes daily sufficient gastric juice to digest all the connective tissue contained in 100 g., or one-quarter of a pound, of cooked beef. The stools of a person eating this quantity should be free from connective tissue, otherwise the secretion is lacking in amount. Naturally, if the meat is uncooked, too much work is required of the stomach; and again, if it is cooked through and through, too little is required—in both cases the test loses its value.

Upon looking at the surface of the liquid stool we may see numerous whitish or yellowish particles. This is the part of the stool of interest to us, for it is the only part which may consist of connective tissue. It may, however, be merely vegetable matter. The differentiation is generally possible without the aid of the microscope. The vegetable particle is apt to be of a yellowish color, as it stains more readily with the bile pigment. Of far greater importance is the fact that upon attempting to disintegrate the particle by means of teasing we find this, in the case of connective tissue, to be very difficult; such tissue is tough and it cannot be divided into many small pieces. If it is first washed and then teased its fibrous nature is often evident. On the other hand, a clump of fat or vegetable matter, although at times firm, never offers the same resistance and is much more readily disintegrated. The differential diagnosis is in most cases possible by this simple method, and naturally becomes easier with practice. It makes very little difference whether we are in doubt as to the identity of one or two small particles if we are able to identify the others, for one or two small tissue bits cannot be considered diagnostic. Sometimes, though rarely, we have to resort to the microscope for diagnosis. This quickly dispels our doubt and allows us to differentiate, for the large cellular vegetable tissue cannot be confounded with the interlacing fibrillar connective tissue bundles. Occasionally, in spite of the diminution of hydrochloric acid the connective tissue does not appear in the stool. However, it never appears if the gastric secretion is normal in amount.

In this simple manner we can diagnose without the use of the stomach tube cases of gastric disturbance combined with diminished secretion of hydrochloric acid, or of achylia gastrica. I have records of many such cases, but shall merely give one illustration.

A patient was admitted to the hospital for emphysema and pleurisy with effusion. He gave a history of having had occasional attacks of diarrhea for the past ten years. An attack of this nature led to our restricting his diet for three days. The macroscopical examination of the stool after this period showed small grayish-white threads scattered throughout, superficially resembling pin-worms. Some small clots of entangled threads were also seen. All these particles were composed of connective tissue. The stomach contents, taken as a control in this case, showed an absence of free hydrochloric acid; total acidity, 15; no lactic acid.

This means of diagnosis is applicable in all cases of suspected diminished gastric secretion from one cause or another, or of achylia. For this latter class of patients it acquires additional value, as these are the very cases in which we find the greatest difficulty in recovering our test meal, owing to the rapid passage of the food into the duodenum. It is especially to be recommended for nervous patients and those who refuse the stomach tube, as well as in all cases where for one reason or another we fear the introduction of the tube into the stomach. I feel convinced that almost every physician can recall cases in his practice where it would have been of the greatest value to have ascertained the amount of hydrochloric acid secreted by the stomach, but where he was prevented by the inability to introduce the tube, or by the inadvisability of so doing.

DIABETES MELLITUS IN CHILDREN.

By H. R. LIVENGOOD, M.D.,

ELIZABETH, N. J.

In looking up the subject of diabetes mellitus in children, I find that Stern could find but thirteen cases reported in children under five years of age, prior to 1902. Having had two such cases come under my observation, I think it might be of interest to report them, together with another case in a child eight years old.

Case number one.—Emma G., aged two years, six months. I first saw this patient on August 12, 1905, and the mother gave me the following history: The child had been ailing for about three months, and had been treated by two other physicians for dyspsepia. Previous to that time she had been considered healthy, except that she had been subject to frequent attacks of bronchitis. The family history was negative, and both parents seemed in perfect health and had but the one child. The child had a voracious appetite, and the mother had indulged it with all sorts of sweetmeats and pastries. The child then began to have intense thirst and frequent urination, and later complained of feeling weak and tired on the least exertion, and began to have frequent attacks of vomiting. The muscles were found flabby and the skin white and clammy. The temperature was normal; the pulse weak and accelerated. The tongue was moist and furred. A few bronchial râles were heard in the chest. The abdomen very much distended and tympanitic. The milk teeth were all decayed. The urine was found to be the typical diabetic urine, with a watery color, acetone odor, and a specific gravity of 1.040. One drop added to 5 c.c. of Fehling's sol. was sufficient to color the mixture with the oxide of copper precipitate. Two quarts of urine were passed in the twenty-four hours. The child was put on a strict diet, and on account of the vomiting and tympanites,

a powder of calomel, salol, and sodium bicarbonate was given. Later on, when these symptoms began to subside, iron, quinine and strychnia were substituted. The child seemed to improve; the thirst and hunger diminished; the frequent urination abated, and the child seemed more playful and active. Amount of urine in twenty-four hours, three pints. Notwithstanding all this, she was seized on the 27th with an attack of vomiting, followed by dyspnea and convulsions, which lasted until midnight, after which she lapsed into coma and died at seven next morning, seventeen days after the first visit.

Case number two.—Reported through kindness of Dr. Strickland of Roselle, N. J. W. A. W., male, aged four years, five months. On January 3, 1897, this patient had the following history: For a week past the child had been noticed to have an enormous appetite, intense thirst, and to have passed large quantities of urine. He had always had good health previously, and never had had any of the infective fevers. The family history also was negative. The symptoms increased and the daily amount of urine averaged four to five quarts. The urination seemed to be increased at night and large quantities were passed every fifteen minutes. This was the characteristic diabetic urine, with a high specific gravity, and containing a large amount of sugar. Coma developed during last twenty-four hours, and the emaciation could be noticed progressing at three hour intervals. Death occurred on the 19th, the child having been sick enough to need medical care seventeen days. The treatment in this case consisted in diet and the administration of brewer's yeast, as long as the child could take it.

Case number three.—Emily O., aged eight years. This patient was seen first by me for her last illness, on August 5, 1905, with almost the same symptoms described in the first case. Here there was no vomiting and the general tone of the body was better. The abdominal distention was well marked and the teeth decayed. Constipation was also present. I had treated this child the previous November for diphtheria, and had given antitoxin, to which the parents had attributed the beginning of the present illness. With this exception the previous and family history were negative. This child was passing over two quarts of urine, with a specific gravity of 1.040 in a single night. She was put on a strict nitrogenous and fatty diet and calomel, salol, and sodium bicarbonate were given for the abdominal condition. Improvement began at once; the appetite and thirst were ameliorated, and the quantity of urine and tympanites lessened. On August 24 the patient weighed forty-two pounds. She passed two quarts of urine in twenty-four hours, with a specific gravity of 1.034. Two minims of Clemen's solution of the bromide of arsenic were given three times a day, and a purgative mineral water to regulate the bowels. On October 28 the weight was forty-six and three-eighth pounds, and the specific gravity of the urine 1.028. On November 23, weight was forty-six and one-half pounds, and the specific gravity of the urine 1.030. It was then impossible to measure the urine, as patient was going to school. She did not have to get up at night to pass it, and went out only once during school hours to pass water. December 10, 1905, the patient had been failing for the past week, and had lost appetite and flesh. Later she vomited. On the evening of the 11th she passed into a comatose state and died the next day at noon. Alkalies were administered during this state by hot rectal injections, with no result. The disease lasted in this case a little over four months.

It will be noticed that in the first and third cases, a marked improvement took place, and the quantity of sugar diminished, although it was never absent. This seemed encouraging at the time to the parents, although I had given them a very bad prognosis. These cases only help to corroborate the prognosis given by Senator and Stern, when they give the mortality at nearly 100 per cent. in children.

1105 East Jersey Street.

MUENSTER AM STEIN.

By B. FERNOW,
NEW YORK.

At the foot of the rocks, upon which stands or stood that "Home of Justice," the castle of Francis von Sickingen, and within view from Rheinstein, the castle of Prince Henry of Prussia, lies surrounded by mountains one of the many spas of the Rhine valley, Muenster am Stein, where every year thousands of patients are sent by their medical advisers for the cure of various ills. The means to effect a cure are both baths in and drinking of the waters. The chief spring pours out water of the temperature of 104° F., and containing in 1,000 parts

Sodium chloride	7.90
Calcium chloride	1.44
Magnesium chloride	0.192
Potassium Chloride	0.174
Lithium chloride	0.07
Strontium chloride	0.0704
Sodium bromide	0.076
Sodium iodide	0.0035
Calcium carbonate	0.145
Iron dioxide	0.0039
Silica	0.009

This hot water is mostly used for bathing, while the five cold springs supply the drinking water for patients, who absorb, in the amount prescribed:

Calcium chloride	228.540
Magnesium chloride	33.423
Strontium chloride	9.000
Potassium chloride	34.280
Sodium chloride	24.010
Lithium chloride	4.001
Magnesium bromide	16.042
Magnesium iodide	0.008

Rubidium and cesium visible in spectrum analysis.

Patients come to this picturesque place to be treated for scrofulous troubles, rickets, skin diseases, uterine disorders and menstrual irregularities, laryngitis, rheumatism, and gout. They are not obliged to leave their hotels or boarding-houses in order to take the prescribed baths or drinks, but can do so before dressing for breakfast or going out. They are offered also a third treatment, that of breathing the salt atmosphere, rich in ozone, for the great saltworks, almost encircling the town, supply this beneficent factor.

Nor is the visitor, who comes with an invalided member of his family, deprived of out-of-door amusements: he or she may, by crossing the Nahe river, encircling the town, wander through the forests at the foot of the mountains without fear of losing a shoe in mud, for the roads are too well built for that. Excursions may be made to a number of historic rivers by the use of bicycles, and everywhere the visitor will find he can taste one of the celebrated Palatinate wines at the source. Living is comparatively cheap. Lodgings may be had for $1.50 a week, and full board for from $1 to $1.50 a day.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 28, 1906.

TREATMENT OF DIFFUSE SEPTIC PERITONITIS.

ALTHOUGH the subject of an untold number of medical monographs and papers, the importance of this question does not permit of flagging interest, and it is well that as much information as possible be gathered and made public. From what has been published it is quite evident that certain methods which not so very long ago were considered faultless are now being again abandoned, and among these is the thorough flushing of the peritoneal cavity in cases of diffuse septic infection, with liberal quantities of sterile saline solution. In spite of its pretended value, even this procedure is accompanied by a mortality of from 70 to 80 per cent., and if the method is critically studied there appear many reasons why this should be so. In the zeal to make the cleansing (?) process complete and thorough, the abdominal contents areu sually subjected to a degree of disturbance which will render null and void all of nature's own efforts at overcoming the infection. And in a pathological process of this character as much dependence must be placed on the body's own system of defense as upon any procedures made use of by the surgeon.

In a recent article, R. G. Le Conte, of Philadelphia (*Annals of Surgery,* February, 1906) directs attention to the excellent technique for cases of septic peritonitis made use of by J. B. Murphy of Chicago, in which all unnecessary and harmful details have been eliminated. The essentials may be summarized in comparatively few words. In the first place, the source of the peritonitis must be rapidly gotten rid of, whether this be a perforated appendix or bowel, a ruptured pus tube, or other similar condition, and this must always be done with the least possible handling of the peritoneal contents. The only permissible drainage is by a tube leading down to the lowest portion of the pelvis, through a suprapubic opening, which, together with that afforded in certain cases by the operative incision, is all-sufficient. All time-consuming procedures during the operation must be eliminated and the position designated by Fowler's name should be assumed after the patient is returned to bed. One of the most novel features of Murphy's method is the slow introduction of large quantities of water into the rectum, at a rate of speed which allows for its immediate absorption. This absorption is claimed to do two things: first, to reverse the current of lymph in the lymphatics of the peritoneum, so that instead of absorption taking place from the peritoneal surface, the mouths of the lymphatics pour out fluid which bathes the peritoneum constantly. The Fowler posture, together with the action of the diaphragm, sends this fluid into the pelvis and this washes the infectious material away in its descent down to a place where it may find its way out through the drainage tube. Then again, the free absorption of fluid from the rectum stimulates the heart and kidneys, and, since it largely increases the amount of urine, it thus eliminates a considerable quantity of septic material which has gained an entrance into the circulation. Another important point in the technique of the treatment is the absolute stoppage of mouth feeding. This checks peristalsis and prevents the dissemination of septic material by the movements of the intestine. The patient will be found to be readily sustained for two days, or even more, by the absorption of water from the rectum, but if deemed advisable small quantities of food may be run in with the irrigating fluid.

There can be little doubt that the method here referred to is absolutely correct from the theoretical standpoint, and those who have tried it are convinced that in practice the theory is fully sustained by the excellent results obtained. It is to be hoped that methods based on the same principles may be more universally adopted and may be found to be productive of good results, for the mortality rates for septic peritonitis are still deplorably high and capable of much improvement.

PROPHYLAXIS OF MALARIA.

THE widespread character and ravages of this disease have called forth numerous efforts at producing an artificial immunity, the majority of which have unfortunately met with little success. Mechanical prophylactic measures directed against mosquitos are no doubt of extreme value, but they are necessarily limited in their application, and particularly in the regions where the disease is endemic the native population cannot be subjected to these restrictions in any considerable number. Attempts to attain a certain degree of immunity by the administration of quinine and other drugs have been received with varying degrees of favor, and many objections have been urged against their use. Professor Celli of Rome, who has had unlimited opportunities for studying the Italian fevers, claims, however, in an article in the *Archiv für Schiffs- und Tropen-Hygiene,* vol. 10, No. 2, that the proper administration of quinine is unsurpassed as a preventive measure. He believes that the failures which have attended this method may be attributed to the administration of an insufficient quantity or to the prolonged intervals between the doses. Thus Koch recommended that the drug be given every seven to ten days, while Celli advises daily doses of from forty to sixty centigrams (six to nine grains) of the bisulphate or the hydrochlorate of quinine in the form of sugar-coated tablets. In Italy the government has been sufficiently impressed by the value of this procedure to provide for the gratuitous distribution of the tablets among the poorer classes of the population.

Contrary to what might be expected, it has been found that all evidence of cinchonism disappears

within four or five days after the beginning of the administration, and no further disturbances of the nervous or digestive systems are evident. On the other hand, where the quinine was given at weekly intervals, the toxic symptoms were produced anew at each administration. The daily use of the drug was accompanied by other advantages, among them a well-marked tonic effect. In addition there was no inhibition of the curative properties of the drug, for it was repeatedly shown that if an individual thus treated in a prophylactic manner became later the subject of an acute malarial attack, the latter was never severe or prolonged, and responded readily to theraupeutic doses of quinine. Celli also found that the various patented derivatives of quinine and the preparations of arsenic or iron so frequently used in chronic malarial poisoning, had practically no effect as prophylactics.

Celli's method must, of course, be merely regarded as a single item in the campaign against malaria, and the sanitary features of the problem must continue to be of prime importance. But while these operations are under way, it is necessary to protect those engaged in the work, and in this particular Celli's suggestions have proved a valuable asset. By keeping the working forces free from the attacks of the disease or by reducing the virulent effects of the latter, a much higher standard of efficiency can be secured. There would appear to be no good reason why this procedure, which Celli claims has been attended with such excellent results in Italy, should not be tried on the Isthmus and in other communities nearer home.

THE PRACTICE OF MEDICINE.

This is the commencement season when the medical colleges all over the country are turning out hundreds of young men grounded in the science of medicine and eager to enter upon their life work. The young graduate of to-day is better trained than were his predecessors of half a century or even a generation ago, but it may be questioned whether he is as fit to care for the sick. The study of medicine is very different from what it was in former times. Then the college was of minor importance. The student passed the greater part of his period of training in the office of some physician and took two courses of lectures in some medical college to supplement the individual teaching of his "preceptor" and as a necessary preliminary to the obtaining of a degree. His office study was eminently practical, he saw his instructor's patients, studied their symptoms under the guidance of the practising physician, and learned from him how to treat them and their diseases. The knowledge he gained in this way was crude, but it was practical. When he became a Doctor of Medicine he was truly a physician, familiar with the multiple aspects of disease and unterrified in its presence. To-day the graduate knows much more of the theory of medicine, he is grounded in pathology and bacteriology and is well up in the symptoms and typical course of a case of typhoid fever or pneumonia; he has attended many clinics and has heard didactic lectures without end on all branches of medical science; but he knows patients only as cases—with the individual sick man he has no acquaintance whatever. This lack must be supplied by a course of interneship in some hospital, and no one to-day thinks of entering upon the practice of his profession without this indispensable training, if it is possible to obtain it.

The motives which induce a man or a woman to take up the study of medicine are varied. Some are attracted by the pure love of science, they are led to enter the profession by a consideration of the opportunities which it offers for original research, just as others are attracted to the study of chemistry or physics or astronomy; such usually devote themselves to laboratory work and are physicians only in virtue of their medical degree. Others practise medicine, but are led to do so by the interest which the observation of morbid action in the human frame excites, they are concerned chiefly with pathology or the action of remedies and are interested in the case rather than the patient; they might just as well be veterinaries except for the accident of having begun their studies in a medical college. Some are induced to enter medicine because they think the title of doctor will give them a certain standing in the community and will raise them in the social scale; these may eventually become true physicians, or they may stick to their calling, after they have become disillusioned as to the position in society which they had hoped to attain, simply because they have no other means of livelihood. Finally others, and these we believe constitute the majority, enter upon the practice of medicine because they love their fellows and hope, through the knowledge which they are to acquire, to be able to reduce the sum of human misery. These are the true physicians whose mission it is to help mankind.

The profession of medicine, even on this higher plane, is nevertheless not entirely altruistic. Those who serve the temple must live by the temple. Life and health are precious and their preservation must be paid for, and this aspect is one that should not be ignored by the young physician. The relation of a physician to his patients is peculiar in that it is intimate and personal, and there is something repugnant to the sensitive man in demanding pay for a work of mercy; but this is a feeling that must be fought against. The practice of medicine is not a trade, but it is a means of livelihood nevertheless, and there is a business side to it which must not be neglected. The laborer is worthy of his hire, and there is no greater laborer than the physician. His entire existence is devoted to the task of saving life, when he can, and to the alleviation of the ills of suffering mankind. For this he asks not riches, but a living wage, and to a living wage he is entitled. We do not mean that he should be hard or actuated by mercenary motives, but he should let it be understood that he knows the value of his services and expects his well-to-do patients to recognize their value. He should keep accurate accounts and present his bills at regular intervals, and insist that these bills are paid and paid promptly. The humanitarian side of medical practice is paramount, but the material side is a close second; indeed, in no other calling are the altruistic and the financial so closely joined; they

are in truth inseparable, though mutually restrictive. If what we must call for want of a better term the commercial side of medical practice is neglected, an injustice is done to the wife and children as well as to the other physicians in the community; if the business side is cultivated too assiduously, the descent into charlatanism is perilously near. The physician should be charitable, but not "easy." A dignified insistence upon due recognition of the worth of his services will not lower him in the estimation of his patients, but will rather increase the respect in which he is held by them.

San Francisco.

It is a cause for wonderment as well as congratulation that the loss of human life in the fearful catastrophe that has laid low the chief city of the Pacific Coast was comparatively so slight. Of course, the exact number of those who perished during the three days' conflagration will never be known, but, large as it may be, it is certainly much smaller than was at first reported. It is appalling to think what it might have been had the earthquake come in the day time when the business section of the city was densely populated. The time for congratulation, however, has not yet come, for there is danger ahead. Those whom the falling walls and the fire have spared are in peril from exposure and contagion. Thousands of homeless wanderers are living in the parks and open spaces, hungry and thirsty, scantily clad, and exposed to the night chill and the rain, and that pneumonia will claim many of them for its own is inevitable. There is, however, a still greater danger which threatens, but which may be averted if heed is paid by those in authority to the counsels of the army surgeons and the physicians in charge of the sanitation of the camps of refuge. Typhoid fever, a preventable disease, is the menace which now hovers over the ruined city, and an epidemic can be averted only by an observance of sanitary laws well known to physicians but only too apt to be disregarded or contemned by laymen in authority, whether military or civil. The dispatches from San Francisco state that the command has been given that all the water used for drinking must be boiled. That is good so far as it goes, yet not altogether reassuring. If this is the only precaution that has been taken it will be unavailing, for the danger lies not in the water supply but in the latrines. Some of those now in the camps of refuge are no doubt sickening with typhoid, if not already attacked. These cannot contaminate the sources of the water supply, but they will surely pollute the soil with their discharges, both alvine and vesical, and unless those are disinfected nothing can prevent a diffusion of the germs of the disease. The lesson of Chickamauga is only eight years old, that of the Russo-Japanese war is but one. We can but hope the officers of the army now in command at the Golden Gate have learned these lessons and have not forgotten them, and that no ignoble jealousies will prevent them from giving full authority to the medical men to carry out the necessary measures of prevention. If an epidemic of typhoid fever breaks out among the refugees in San Francisco's parks, it will be easy to place the responsibility, and those who may have hindered the work of sanitation must and will be held to a strict accountability for the needless sacrifice of life.

The Fifteenth International Medical Congress.

Held in Lisbon, April 19-26, 1906.

(Special Cable Report to the Medical Record.)

The Fifteenth International Medical Congress was formally opened by the King of Portugal in person on the afternoon of April 19. The large hall of the Geographical Society, where the session was held, was thronged with members of the Congress and citizens of Lisbon, among the latter being many ladies. The King welcomed the congressists in the name of Portugal. Physicians, he said, were occupied with the most beautiful and noblest of tasks—the healing of the physical ills of mankind. He hoped that the deliberations of the Congress, which he had the pleasure of now declaring open, would be fruitful in the discovery and promulgation of new facts in medical science whereby the life of man on earth could be made longer, stronger, and yet more restful. Portugal, ever mindful of her duty to the world at large, prized the work of medical men which had already been of such signal benefit to the human race, and admired, honored, and furthered this noble science. The Queen then arose, amidst great applause, and spoke a few words expressive of her thanks for the honorary presidency to which she had been elected.

The President of the Congress, Councillor Costa Alemao, then delivered an address. He first thanked the King and Queen, who had so graciously cooperated with those engaged in the war against tuberculosis and had lent their powerful aid in furtherance of the movement, for the interest which they had also manifested in the work of the Congress. He welcomed the foreign guests and also his Portuguese colleagues. These latter, he said, had not gained renown for any notable discoveries in medicine, yet they were earnest students of the science, and diligently clutivated the art, as the congressists would see when they visited the clinics of the city. The success of the present Congress was dependent upon the members themselves, and the speaker hoped for great results of their deliberations. Medicine had made great strides since the Madrid Congress, among the most notable discoveries being that of the etiological factors of syphilis and of sleeping sickness, and they might with confidence look forward to discoveries of equal or greater moment in the future. The announcement by Behring at the International Tuberculosis Congress in Paris was full of promise, and one could but hope that his discovery would be productive of good results. The solution of the tuberculosis problem, the speaker believed, was to be found in these international congresses, where the individual workers could compare their experiences and publish their discoveries. In closing, the speaker expressed his thanks for the great honor which he had received in being made president of this international gathering of scientists, and he prayed with all his heart for the success of the meeting.

Dr. Miguel Bombarda, Secretary of the Congress, then presented his report. The number of registered members was 1,818, of whom 145 were from Germany, 221 from France, 124 from England, and 55 from the United States. The program contained the titles of 500 papers on 134 distinct subjects which were to be read in the 20 sections of the Congress.

Then followed brief addresses by the official representatives of all the countries of the civilized world, in which the speakers expressed their pleasure in being able to greet their colleagues from other lands

and uttered wishes for the success of the Congress. Dr. Richardson, speaking for the United States, expressed the friendship of his government for the Royal Couple and its good wishes for the assembled congressists. He then congratulated the Congress on its privilege in meeting in beautiful Portugal, and especially in the attractive city of Lisbon. Success under such distinguished patronage as that of the King and Queen, and surrounded by such auspicious circumstances, could not be doubted. Dr. Posner of Berlin, editor of the *Berliner klinische Wochenschrift,* spoke briefly in the name of the medical press.

In the evening the members of the Congress were entertained at a reception given by Dr. Costa Alemao, the President of the Congress, in the hall of the School of Medicine.

At the general session held on April 21, Dr. Brissaud of Paris delivered a public address on "Infantilism."

News of the Week.

Red Cross Appeal.—The New York State branch of the American Red Cross appeals for financial aid for the sufferers from the famine in Japan, for the victims of the eruption of Vesuvius, and, most urgently, for the homeless citizens of San Francisco. It is stated that the organization of the Red Cross societies is now perfected to such a degree that all of the sums contributed can be devoted in their entirety to the actual relief of the needy without diverting any amounts to cover the expenses of distribution. The society also appeals for members for the New York State branch to contribute a dollar each yearly to establish a great emergency fund. It also desires to enroll members who will be ready to volunteer as physicians, nurses, and field or executive workers in times of crisis. Contributions for either relief fund should be addressed to Jacob H. Schiff, Room 509, No. 500 Fifth avenue, plainly marked "For San Francisco," "For Italy," or "For Japan." These will be duly acknowledged. Applications for membership should be made to William Chauncy Langdon, Room 509, No. 500 Fifth avenue. Yearly membership is $1; life membership, $25. The work in San Francisco will be in charge of Dr. E. T. Devine, secretary of the New York Charity Organization Society, who has been sent to California together with Miss Lucile Eaves, who was for a number of years head worker at Park Settlement of San Francisco, which is in the heart of the stricken district. The charitable are also asked to send food, clothing, etc., to California. All such articles should be sent to the express offices, distinctly labeled, "For the Red Cross Relief, San Francisco, California." The companies will then transport these contributions without charge. Two copies of the invoice should be sent to the office of the New York Red Cross; one will be filed and acknowledged, and the other sent to Dr. Devine.

Death of Professor Curie.—Professor Pierre Curie, the discoverer of radium, was run over and killed in Paris on April 19. Professor Curie was the son of a physician and was born in Paris in 1859. He was educated at the Sorbonne and was given a chair in the School of Chemistry in Paris in 1895. Together with his wife, who was professor of physics in the Sèvres High School, he spent several years investigating uranium and thorium, and in 1898 they were able to announce the discovery of a new and strongly radioactive substance in pitchblende. In 1901 M. Curie received the La Caze prize of 10,000 francs from the French Academy of Sciences, and in 1903 the couple were awarded the Noble prize for chemistry, followed shortly afterwards by the sum of 60,000 francs as part of the Osiris prize of France, all in recognition of their work on radium.

St. Luke's Hospital Alumni.—At the annual dinner of the Society of the Alumni of St. Luke's Hospital, in this city, on April 21, Dr. Lewellys Barker, Professor of Medicine, Johns Hopkins University as guest of honor, delivered an address on "The Duty of Hospitals to Medical Education."

A Course of Lectures on Hydrotherapy is being delivered by Dr. Simon Baruch at the Medical Department of Columbia University in this city. This course of lectures constitutes, we believe, the first special teaching on hydrotherapy in any university in an English-speaking country, although the subject has long been taught from special chairs in the larger universities in Germany and Italy. Dr. Baruch's course marks a distinct advance in practical therapeutic teaching in this country.

Hospital Conference.—At a meeting held in the Academy of Medicine on April 18 representatives of thirty-eight hospitals adopted a permanent organization for the hospital conference of the City of New York. The constitution states that the object of the organization is the prevention of extravagance and waste in hospital maintenance. The following were elected as officers: *President,* the Rev. George F. Clover of St. Luke's; *First Vice-President,* Richard Townley of J. Hood Wright; *Second Vice-President,* Mrs. A. M. Lawton, General Memorial; *Secretary,* Dr. S. S. Goldwater, Mount Sinai; *Treasurer,* A. H. Harrington, New York Eye and Ear Hospital. Any hospital with not less than thirty free beds may send two representatives to the conferences, and circular letters of questions relating to matters of hospital management are to be prepared and sent to the superintendents of a large number of hospitals.

Reduced Mortality Rate in Chicago.—A reduction in the number of infectious diseases reported has been noted, most markedly in Bright's disease, bronchitis, cancer, consumption, and typhoid fever. The mortality from the infectious diseases of childhood—diptheria, scarlet fever, and whooping cough—shows an increase, and the ratio of deaths among the aged, those over 60 years old, still remains abnormally high, although slightly lower than during the week previous.

Honor to Professor Trendelenburg.—In honor of Professor Trendelenburg of Leipzig, the German Medical Society has arranged a special meeting at the Academy of Medicine, on Monday, April 30. Professor Trendelenburg will deliver an address, and several surgeons of this city will present patients. The discussions will be in German and English. A reception was given to Dr. Trendelenburg at Delmonico's on the evening of April 27, by Dr. Willy Meyer.

Positions in the New Fordham Hospital.—The Board of Trustees of Bellevue and Allied Hospitals expect to open a department for out-patients in connection with the new Fordham Hospital, at the west side of Crotonia avenue and Southern Boulevard, opposite the north end of Cambreling avenue, now rapidly approaching completion. Applications for positions in this department will be received by the Board of Trustees, which is desirous of having as wide a field as possible from which to make selection for these positions.

New York State Department of Health Reports.—Ophthalmia neonatorum has been added to the number of diseases to be reported monthly to the State Department of Health by the local health officers. The other diseases on this list are diphtheria, scarlatina, smallpox, typhoid fever, measles, cerebrospinal meningitis, and pulmonary tuberculosis.

Dr. W. P. Spratling of Sonyea, N. Y., owing to unwarranted use that has been made of his name, requests us to announce that he has no connection with any private institution for the care and treatment of epileptics.

Hospital Internes in Chicago.—Fifty-three physicians passed the civil service examination for appointment as internes in the County Hospital and Cook County Institutions, Dunning, Illinois. Forty of this number will be appointed to positions within the next nine months, the first appointments being made at Cook County Hospital in June.

Dr. M. Reichmann of Chicago has been appointed radiographer to the Alexian Brothers' Hospital, of that city.

Commencement Exercises.—At the seventy-sixth annual commencement of the Medical College of the State of South Carolina eight candidates in medicine and twenty-nine in pharmacy were graduated. On April 12 the degree of M.D. was conferred on twenty-six members of the senior class of the University of Arkansas Medical Department, and at its forty-first annual commencement, on April 9, the Alabama Medical College graduated a class of twenty-eight members.

In Honor of Nothnagel.—A statue of the eminent Viennese clinician is to be erected in the court of the university, and a fund is being collected, the revenue from which is to be used as an annual prize to be awarded to the speaker selected each year to deliver a lecture in memory of Nothnagel, in the deceased teacher's lecture room.

Ziegler's Successor.—The Chair of Pathology at the University of Freiburg, which was formerly occupied by Professor Ziegler, was offered to Professor Schmorl, who declined it, however, owing to considerations of health. It was then offered to Professor Aschoff of Marburg, who has accepted it.

Free Alcohol Bill.—On April 17 the free alcohol bill was passed by the House of Representatives by a vote of 224 to 7.

The National Quarantine Bill with amendment was passed by the House of Representatives on April 16.

Florida State Medical Association.—At the annual convention of this society, held at Gainesville on April 18 to 20, the subject of life insurance examinations was taken up and it was decided that no members of the State or county societies would make such examinations, including analysis of the urine, for less than $5.00. Tampa was chosen as the next place of meeting, on the third Wednesday, Thursday, and Friday of April, 1907. The following officers were elected: *President*, Dr. John D. McDiarmid of DeLand; *First Vice-President*, Dr. J. Lawrence of Tampa; *Second Vice-President*, Dr. S. R. Mallory Kennedy of Pensacola; *Third Vice-President*, Dr. J. M. Dell of Gainesville; *Secretary and Treasurer*, Dr. J. D. Fernandez of Jacksonville.

West Virginia State Medical Association.—The thirty-ninth annual meeting of this society will be held at Webster Springs, W. Va., June 20, 21, and 22, 1906. The secretary is Dr. W. W. Golden, Elkins, W. Va.

Tennessee State Medical Association.—At the annual meeting in Memphis on April 12 the election of officers resulted as follows: *President*, Dr. L. A. Yarbrough of Covington; *First Vice-President*, Dr. J. L. Andrews of Memphis; *Second Vice-President*, Dr. Hazle Padgett of Nashville; *Third Vice-President*, Dr. J. R. Rathwell of Chattanooga; *Secretary*, Dr. George H. Price of Nashville; *Treasurer*, Dr. V. C. Bilbro of Murfreesboro.

Hampden District (Mass.) Medical Society.—At the annual meeting of this society, held on April 17, at Springfield, the following officers were elected: *President*, Dr. E. H. Guild of Springfield; *Vice-President*, Dr. D. F. Donoghue of Holyoke; *Secretary and Treasurer*, Dr. F. S. Ward of Springfield.

Tolland County (Conn.) Medical Association.—The following were elected as officers at the 114th annual meeting of this society, held at Rockville on April 17: *President*, Dr. F. W. Walsh of Rockville; *Vice-President*, Dr. T. F. Rockwell; *Clerk*, Dr. T. F. O'Loughlin; *Counselor*, Dr. C. N. Newton of Stafford.

Richardson County (Neb.) Medical Association.—Officers were elected as follows at the annual meeting of this society, held on April 10, at Falls City: *President*, Dr. E. C. Wittwer of Humboldt; *Vice-President*, Dr. J. R. Morris of Humboldt; *Secretary*, Dr. C. T. Burchard of Falls City; *Censor*, Dr. G. G. Gandy of Humboldt; *State Delegate*, Dr. M. L. Wilson of Humboldt.

Brockton (Mass.) Medical Society.—At the annual meeting, on April 13, of this society, officers were elected as follows: *President*, Dr. J. M. Morin; *Vice-President*, Dr. J. H. Lawrence; *Secretary*, Dr. R. A. Elliott; *Treasurer*, Dr. E. E. Goodwin.

Cass County (Ill.) Medical Society.—The Cass County Medical society, at a meeting held in Virginia on April 11, elected the following: *President*, Dr. O. M. Hubbard of Virginia; *Vice-President*, Dr. Darwin Gailey of Ashland; *Secretary*, Dr. J. A. McGee of Virginia; *Treasurer*, Dr. Albert Lyles of Virginia.

Obituary Notes.—Dr. Matthew T. Gaffney of Newark, N. J., died on April 17, at the age of thirty-six years. He was a graduate of the College of Physicians and Surgeons in this city.

Dr. Joseph Hedges of Orange, N. J., died on April 14, after an illness of several weeks. Dr. Hedges was in his seventy-ninth year.

Dr. Louis Mackall of Washington, D. C., died on April 18, at the age of seventy-five years. He was born in Prince George County, Md., and was graduated from Georgetown College and the University of Maryland. He began to practise in Georgetown in 1851 and was prominently identified with the medical societies and hospitals of Washington.

Dr. Ira C. Sawyer of Springvale, Me., died on April 13, of heart failure, at the age of sixty-six years. Dr. Sawyer was born in Hiram, Me., and was graduated from Dartmouth College in 1863. He had practised in Springvale since 1884.

Dr. Stephen E. Wentworth of Auburn, Me., died on April 10, of heart failure, at the age of sixty-nine years. He was born in Limington, Me., in 1837, and was graduated from the Bowdoin Medical School in 1868. He began his professional work in Brownville and Lovell, but had practised in Auburn for the past thirty-two years.

Special Article.

OPPORTUNITIES FOR THE RECENT GRADUATE.

In a short time the various medical colleges throughout the country will be turning out innumerable graduates to swell the ranks of an already overcrowded profession. What is going to become of this new contingent? What are they going to do? In the first place they will learn that the public has not been most anxiously awaiting the display of their shingle; and they will also learn that, generally speaking, in the first years of medical practice leisure time is plentiful and dollars are few. Building up a practice is slow and uphill work, and it is not easy to make a living. Of course, there will be a few who have judiciously selected their parents and their social position in the world; these favored ones will either be taken under the wing of some popular and successful practitioner, or they will leisurely continue their studies and wait for the growth of their practice without having to take any thought as to the earning of a living. In their case this latter is unnecessary. But the ninety and nine who are not so fortunate, what is to become of them? Fortunately, there are various methods which may help some of these along the early years of their chosen career, or even prove to be a permanent means of support. In the first place, the recent graduate may cast his eyes toward the public services, which will furnish him with a living salary from the beginning; but these should be entered only with the idea of making them a life work. The man who enters the Army, the Navy, or the Marine-Hospital Service with the idea of remaining there only a few years and then resigning to enter upon private practice, makes a fatal mistake. The training he receives in these services is not well adapted to fit him for civil practice, and his salary in the early years is hardly more than enough for daily needs, so that it will be practically impossible for him to save a sum sufficient for support during the waiting period. We will say a few words about each of these services in order.

The Army Medical Service.—In order to secure an appointment in the Army Medical Service, it is first necessary for the applicant to be a graduate of a reputable medical college, to be a citizen of the United States, and to be between twenty-two and twenty-nine years of age. He will have to undergo a thorough physical examination; he must be not less than five feet four inches in height, of well-developed physique, and of dignified bearing; he must labor under no mental or physical infirmity which will interfere with the efficient performance of any duty that may be assigned to him. Slight errors of refraction when not accompanied by ocular disease and when capable of correction by glasses, are not cause for rejection. Permission to appear before the Army Medical Board must be obtained by letter to the Secretary of War. The letter must be in the handwriting of the applicant, must give the place and date of birth, his permanent residence, and two certified letters from reputable persons as to his citizenship, habits, and character. A personal investigation of his antecedents, morals, etc., is made by Army Officers acting under instructions from higher authorities. After the applicant has passed a satisfactory examination before the Army Medical Board, and has been recommended by the Surgeon-General, he is eligible. The appointments are made by the President. The professional examination is both oral and written; it includes anatomy, physiology, chemistry, hygiene, pathology, bacteriology, therapeutics, materia medica, surgery, practice, obstetrics, and the diseases of women and children. The papers require about a half day each, that is about two hours writing and half hour oral, and are free from catch questions. The applicant must then pass a satisfactory examination in clinical work and operations on the cadaver. He must also present evidence that he has had one year's hospital experience, or its equivalent in practice. The first appointment entitles the physician to the grade of Assistant Surgeon with the rank of first lieutenant, and a salary of $1,600 per annum. At the end of five years he is promoted to Captain, and receives $2,000 a year, which, with a 10 per cent. service increase is $2,200. After ten years' service, this pay becomes $2,400 per annum. The pay attached to the grade of Major is $2,500 per annum, with 10 per cent. added for each five years of service. Lieutenant-colonel receives $4,000; Colonel, $4,500; and Brigadier-general $5,500. In addition to the above amounts, all officers on duty outside the United States receive a further increase of 10 per cent. on their pay, while so serving. Officers are also furnished either with comfortable quarters, or liberal money allowance in lieu thereof. When traveling on duty, they are allowed mileage at seven cents a mile; they are also entitled to transportation for professional books and papers, and for a reasonable amount of baggage; forage, stabling, and transportation for two horses are also provided. Books, instruments, and appliances for use in the performance of their duties are furnished by the Government. Groceries, fuel, etc., are furnished from the Commissary at wholesale prices. A fixed home is out of the question; the Army Surgeon must move about as the needs of the service require. The social side of army life forms a most pleasant feature of military service; the popularity of the surgeon will depend largely upon his own attributes and personality. Leave of absence on full pay is allowed for one month every year, and this may accumulate to four months as a continuous leave. This leave may be lengthened, by permission, with half pay. Medical officers are entitled to the privilege of retirement at any time for disability incurred in the line of duty, or after forty years' service. On attaining the age of sixty-four years, they are placed on the retired list by operation of law. Retired officers receive three-fourths the amount of their pay in effect at the time of their retirement; a sufficient income being thus provided for support in case of disability contracted in the service or for old age. In the case of a medical officer retired as a colonel, his retired pay would thus amount to $3,375 annually—which would be a fair interest on $75,000, or a greater sum than the average physician in civil life could hope to amass in a long life of professional activity. In case of death due to causes incident to the service, a pension is granted to the dependent members of the deceased officer's family. This pension in the case of an officer of the rank of lieutenant-colonel amounts to $360 annually, with $24 for each minor child. This sum, though small, is about the interest on a life insurance policy of $9,000. The army surgeon is offered every opportunity to win a name in medical science. While his work is restricted in some of the branches, he has ample opportunities in the surgical field, in the study of tropical diseases, and in experimental research work. The authorities are always willing to furnish any special apparatus, laboratory

appliances, etc., to those who give promise of being a credit to their profession. Examinations for the Army Medical Service are held in Washington, San Francisco, and Manila. No political influence is either necessary or desirable, as the appointments are made entirely upon merit. We understand that there are at present twenty-five vacancies in the medical corps of the army.

The Naval Medical Service.—The bureau system of the Navy Department was not inaugurated until 1842, and it was at that late date that the corps arrived at the dignity of having a medical officer at its head. From that time to this it has gradually developed; the corps now consisting of about two hundred and twenty members, with provision of law enacted to bring the number up to three hundred and forty-seven by 1909.

The following table shows the grades, rank, and number in each grade of the corps as it will be at the end of 1908 under the present legal provisions:

NUMBER	GRADE	RANK	EQUIVALENT ARMY RANK
15	Medical director	Captain	Colonel
15	Medical inspector	Commander	Lieutenant-colonel
85	Surgeon	Lieutenant-com'd'r	Major
230	Passed assistant surgeon and assistant surgeon	Lieutenant	Captain
		Lieutenant, junior	First lieutenant

In addition to the above a list of twenty-five acting assistant surgeons forms part of the medical corps; these are employed for temporary service only, for a term of three years. The highest official honor to which a naval medical officer can aspire is that of surgeon-general and chief of the bureau of medicine and surgery, and he holds the rank of rear-admiral while in office. The appointment is made by the President, and is good for a period of four years. Physicians desiring to enter the service must make application by letter to the Secretary of the Navy. They must present one or more certified letters from citizens as to their moral character, they must be between twenty-one and thirty years of age, and citizens of the United States. The applicant has to undergo a thorough physical examination; errors of refraction, when correctable, are not cause for rejection. The professional examination is both oral and written; a grade of 80 per cent. has to be obtained in each of the following subjects: Anatomy, physiology, surgery, medicine, materia medica, and therapeutics; 70 per cent in pathology and microscopy and 60 per cent. in chemistry and physics, obstetrics, and jurisprudence. Besides the written examination, there are practical tests in the application of bandages and splints, operative work on the cadaver, etc. The preliminary requirements are those which every physician should possess. The board of examiners is practically in continuous session; the examinations are held in Washington, D. C., and at the U. S. Naval Hospital, Mare's Island, Cal. The following table shows the remuneration:

	AT SEA	ON SHORE*	ALLOWANCES PER ANNUM*
Assistant surgeons, rank of lieutenant (junior grade)	$1,760.00	$1,496.00	$288.00
Passed assistant surgeons, rank of lieutenant	2,200.00	1,870.00	432.00
After five years in the service	2,400.00	2,040.00	432.00
After ten years in the service	2,600.00	2,210.00	432.00
Surgeons, rank of lieut.-commander.			
After ten years in the service	3,250.00	2,762.50	576.00
After fifteen years in the service.	3,500.00	2,975.00	576.00
Medical inspectors, rank of comm'd'r:			
After fifteen years in the service.	4,000.00	3,400.00	576.00
Medical directors, rank of captain:			
After fifteen years in the service.	4,500.00	3,825.00	720.00
Surgeon-general, rank of rear-adm'al.	5,500.00	5,500.00	720.00

Only when quarters are not furnished by the Government.
*Eight cents per mile is the allowance when traveling under orders.

All officers are retired from active service at the age of sixty-two years, on three-fourths of the full sea pay of their grade; so, too, any officers becoming incapacitated during service are entitled to three-fourths full pay. Assistant surgeons are promoted at the end of three years' service to the grade of passed assistant; the higher offices are obtained by examination, and in the order of seniority. After acceptance, the young officer is ordered to one of the fourteen naval hospitals, where he undergoes a five months' post-graduate course along special lines to fit him for his work; he is then assigned to sea duty. The vessels usually carry from seven hundred to eight hundred men, the modern vessels are fitted with hospital quarters, isolation quarters, laboratory, and the most recent books and instruments; and the young officer is encouraged to pursue research work. Frequently he is detailed for duty at one of the stations abroad. The duties of the medical officer become more responsible as his rank increases; from the small vessel he is promoted to a larger one until he reaches the grade of medical inspector, when he has charge of a fleet, or of one of the large navy yards. As medical director his duties are confined to shore service, either in one of the larger hospitals, as a member of some important board, or as instructor in the naval medical school. The young man about to enter upon a naval career must not lose sight of the fact that the home is practically lost; he must be willing to live in a contracted space and in unwholesome parts of the world. If he has strong domestic tastes he should not enter the service, for, as age creeps on these discomforts weigh heavily; and to such a one it is doubtful if the pleasures incident to the life are sufficient to counterbalance the discomforts.

The Public Health and Marine-Hospital Service.—This is a bureau of the Treasury Department. There are many duties connected with the department, among them the management and suppression of epidemics, inspection of immigrants, investigation of sanitary problems, conducting quarantine stations, the inspection of all establishments manufacturing viruses, serums, toxins, and analogous products, and the maintenance of the Sanatorium for consumptives at Fort Stanton, New Mexico. In short, the Public Health and Marine-Hospital Service acts as a national board of health. To enter the service the candidate must be a citizen, between twenty-two and thirty years of age, and a graduate of a reputable medical college. He must pass a satisfactory physical examination, and give evidence in an oral and written examination of a thorough knowledge of the academic branches. He is required to pass a written examination in anatomy, physiology, chemistry, materia medica, practice, surgery, obstetrics and diseases of women, hygiene, pathology, and bacteriology. He may also be called upon for operative work upon the cadaver, microscopical work, and bandaging. An average of 80 per cent. is required; the applicant failing is entitled to a second, but not to a third trial. Having passed successfully, the applicant is commissioned by the President, by and with the advice and consent of the senate, as an assistant surgeon with salary of $1,600 per annum. After five years' satisfactory service he is examined for promotion to the grade of passed assistant surgeon with compensation of $2,000. The higher offices are filled by examination when a vacancy occurs. All officers in the service above the rank of assistant surgeon receive 10 per cent. increase of their annual salary after each five years of ser-

vice. Comfortable quarters are provided in almost all the quarantine and hospital stations. Where no quarters are provided officers receive commutation as follows:

	AT HOME	ABROAD
Assistant surgeons	$30 per month	$80 per month
Passed assistant surgeons	$40 " "	$85 " "
Surgeons	$50 " "	$90 " "

Five dollars a day is allowed medical officers for traveling expenses and hotel bills, when traveling under orders. Officers and their families are entitled to medical supplies. Thirty days leave of absence are allowed each year, or the leave may be allowed to accumulate till four months may be had with full pay. Officers stationed on shore may conduct a private practice provided it in nowise conflicts with their government duties. The service consists of a hundred and eight commissioned medical officers. The medical officers have rare opportunities to study strange and unusual affections unknown in our climate, and also have vast opportunities in a surgical line. The younger officers of the service are detailed to the hygienic laboratory at Washington for a post-graduate course in pathology, bacteriology, and various branches of sanitary science. The service offers many opportunities for seeing the world, as hospitals are conducted in the Philippines, Porto Rico, and Hawaii; three officers are stationed in Japan, two in China, ten in Cuba, besides many at other ports in Europe and elsewhere.

We repeat that a man who enters either of these services should do so with the expectation of making it his life work. Therefore it would be well for intending applicants to cultivate the acquaintance of some one who is actively engaged in the service to which he aspires, and to gain some inside information with regard to expenses, quarters, comradeship, society, and many other things that are of real importance, but which do not generally figure on official notices.

In addition to the public services just mentioned there are opportunities which may offer a temporary assistance, and as such be of great value in enabling the young physician to live while his practice is growing. The various municipal appointments would fall under this head; and before going into any detail with regard to these, it should be emphatically understood that in order to succeed in general practice these various helps must be dropped at the earliest possible moment. In this they differ *in toto* from the public services.

The applicant usually turns first to the municipal **Health Department.** In large cities there is often room here for many men. Take New York City for example; upward of two hundred and forty physicians are on salary; and in addition, numerous temporary appointments are made as occasion and emergency require. The positions offering constant employment to physicians, with the yearly salaries attached, are as follows: A general medical officer, $5,000; a sanitary superintendent, $5,000; five assistant sanitary superintendents, $3,500; two chief inspectors of contagious diseases, $3,000 and $2,500; one assistant chief inspector of contagious diseases, $2,550; fourteen diagnosticians, $1,200 to $1,800; 170 medical inspectors, $1,200 to $1,800; fifty-two sanitary inspectors (one-half of these may be physicians), $750 to $1,800; one superintendent of hospitals, $2,500; three hospital physicians, $1,800; three assistant hospital physicians, $1,200; one registrar of records, $4,000; four assistant registrars of records, $3,000; one assistant director of the bacteriological laboratories, $2,110; one assistant director of the vaccine laboratory, $1,800; one assistant director of the diagnosis laboratory, $1,800; twelve assistant bacteriologists, $1,200. As stated, temporary appointments may be made in any of the divisions, physicians thus appointed drawing salary for the term of employment at the same ratio that the permanent employees in similar positions receive. All positions except the first four named are competitive and come under the civil service law. In order to be placed upon the eligible list for the above positions the candidate must make 75 per cent. on the technical paper, those making the highest percentage being placed on the eligible list. In making the appointment three names from the top of the list are submitted by the civil service commission to the appointing power. One is chosen, and the remaining two names are replaced on the list in the position they originally held. All applicants must be registered physicians in the city of New York, and should be specially qualified in reference to contagious diseases and sanitary science. Those applying for positions in the bacteriological department should have had laboratory training. Similar rules prevail regarding the health departments in other cities.

Duties of the Medical Inspector.—He is assigned a district, and receives daily notification from the chief inspector concerning the location of all contagious cases reported therein, and it is his duty to visit these patients within twenty-four hours after receiving notification, and to enforce the rules of the department relative thereto. He must revisit the patient at frequent intervals to see that the regulations are being adhered to; and, at the conclusion of the case he arranges for the disinfection of the premises, and the return to school of the children who have been detained therefrom. It is the duty of the school inspectors to visit their schools daily, and to examine the pupils carefully for any evidence of contagious diseases, eye diseases, and skin diseases, and to exclude at once those who give evidence of them.

Vaccination.—The inspector is given a district which he is supposed to canvass daily, he should report at least one hundred cases per week. In case of epidemics he does special work in any part of the city to which he may be ordered. It is also the duty of the medical inspectors to visit the sick of the tenement house districts and to investigate citizens' complaints regarding the violation of sanitary ordinances. They are supposed to devote eight hours a day to the work. *Diagnosticians* make the official diagnosis for the department. They have their districts and are sent to every case reported therein in which removal to the contagious disease hospital is requested or necessary. They also discharge the patients from the department hospitals at the expiration of their sickness. *The superintendent of hospitals* has charge of the business end of the department hospitals and is the immediate superior of the hospital physician and his assistant, whose duties are similar to those of the ordinary resident physicians in any general hospital. *The registrar of records* and his assistants have entire charge of the vital statistics of the department and the reception and granting of death certificates, burial permits, etc. The three *assistant directors of the bacteriological laboratories* superintend the work of the research, vaccine, and diagnosis laboratories

respectively, and the assistant bacteriologists are assigned to work in either of these three divisions. The work in the *research laboratory* comprises the manufacture of the various antitoxins prepared by the department and also research along such lines as may be suggested by the assistant director in charge. The work in the *vaccine laboratory* is limited to the production of vaccine. The *diagnosis laboratory* deals with the examination of diphtheria cultures, Widal tests, examinations for the malarial organism, and such other bacteriological diagnostic work as may be required by the assistant director in charge. With respect to the time required for the satisfactory performance of the duties of any of these positions, it may be said that the sanitary superintendent, the chief and assistant chief inspector of contagious diseases, the registrar and his assistants, the superintendent of hospitals, together with the hospital physician and his assistant, the assistant directors of the bacteriological laboratories and the assistant bacteriologists, with the exception of those employed in the diagnosis laboratory, are forced to give their entire time to the service of the department, at least to the extent of eight hours per day. The time required in the other positions is extremely variable, and depends largely upon the time of year and many contingent circumstances. In general it may be said that it varies from three to eight hours per day. The work of diagnostician, medical inspector, and medical sanitary inspector does not prevent the holders of such positions from practising medicine, nor does it materially interfere with a limited carrying out of the same. Positions most suitable for new appointees are those of medical inspector, medical sanitary inspector, assistant bacteriologist, and hospital or assistant hospital physicians. For appointment to any of the other positions previous experience in the workings of the department is necessary.

The Street Cleaning Department.—There are only three salaried positions open to medical men in the New York City street-cleaning department. The salary of these examiners is $1,200 per year, and from two to three hours daily work is required. It is their duty to visit sick members of the force, and to report as to the probable duration of the illness; also to examine the uniformed members of the force with respect to their ability to perform various duties. They are civil-service positions.

Tenement House Commission.—Two or three physicians are employed in this department in New York at a salary of $1,200 yearly, from four to eight hours' work a day being required. Their duties consist essentially in a supervision of the execution of the sanitary code relating to tenement houses.

In The Department of Public Charities and Correction, the physician's entire time is expected, as the billets are mainly hospital positions paying from $500 to $1,500 a year. There is also the position of visiting physician to the city jails and penitentiaries at a salary of $1,000 to $2,000 yearly, and requiring about four hours' time.

Quarantine and Immigration Service.—In all seaports there is a health officer of the port appointed by the Governor of the State. The health officer appoints as many deputies as are necessary, and it is the duty of one of these deputies to act as house physician to the quarantine hospital, while the other deputies board incoming vessels and examine the passengers and crew. In New York the deputies receive $3,000 per year.

In the Immigration Bureau the positions come under the government civil service, and the appointments are made by the surgeon-general of the Public Health and Marine-Hospital Service. The salary is from $1,200 to $2,500 per year and the deputies are expected to devote all of their time to the work. It is their duty to examine every person arriving at the port, and to detain all suspicious cases. In the event of contagious diseases breaking out, the patients are conveyed to the Hospital for Contagious Diseases.

Corporations and Business Houses.—In recent years manufacturing concerns, street railway corporations, and the department stores have been employing physicians. These positions are obtained through personal influence. In the last-named capacity the salary is small, not more than $1,200 yearly and most of the day is occupied at the store. The street railways pay from $1,200 to $2,000; and the work can usually be accomplished in from three to four hours daily. The physician is called upon to examine and give medical service to any person injured in any way by vehicles of the corporation; and to examine such persons as the company may desire with a view to giving expert testimony in the event of a lawsuit.

Physicians to manufacturing concerns are supposed to treat any employe injured in the discharge of duty. The salary is from $500 to $1,200.

The Race Track.—Physicians are employed by the different jockey clubs to be present at the races and render services to the jockeys or other employees who may be injured. The salary is $100 per month during the season.

Medical Literary Work.—In order to obtain employment here the physician must have special ability; there is a wide range of work extending from proof reading or reading of manuscripts to the editorship of a medical periodical. The recent graduate may as well be warned, however, that there is no demand for translation of books. Much of the journalistic work is paid for by the piece; but occasionally salaries are paid, varying from $300 or less, to several thousands a year. This is pleasant occupation in that, in general, one is not bound by regular hours, and it further compels a man to keep in touch with the most recent advances in medicine. It calls, however, for ability of a peculiar character, and in certain emergencies the work is very exacting. The opportunities for such work are few.

Detailing.—Oftentimes an energetic and tactful man will have no difficulty in securing a position with one of the proprietary drug companies, wholesale drug houses, medical book firms, or instrument makers. The work in either of the first two instances is practically the same. The physician is assigned a territory; he then obtains a list of those whom he seeks to interview and interest. The detailer, in order to be successful, must cultivate courtesy and patience; he may often find it necessary to call three or four times at the same office before obtaining an interview. Salaries may vary from $50 to $125 a month, with expenses; physicians are expected to pay a certain number of visits a day, and to send in reports at specified times. The representatives of the book firms and instrument makers carry samples of their goods with them, and solicit orders for the same. They sometimes obtain a stated salary; but as a rule they are assigned a territory, their expenses are paid, and they receive a commission on the sales. The detailers and

agents find the work pleasant and fairly remunerative. It gives the young physician an excellent opportunity to study the manners and customs of the different professional men with whom he comes in contact, besides enabling him to watch for a good location without any personal expense. As soon as the latter is found, he should avail himself of it; for while the work is easy and pleasant, it becomes monotonous sooner or later.

Lodge Practice.—In the last two decades it has become an almost universal custom in all concerns employing very many people to form a beneficiary association. The members are taxed from one to two dollars a year; this sum is paid over to some physician who contracts to care for all the members. In some cases he also attends the families of the members for one-half his usual rate. This system has many disadvantages, and cannot be recommended; still there are always applicants for the positions.

We come now to the last class, namely those appointments which offer a more or less permanent supplement to the income from private practice, such as appointments as insurance examiners, railway surgeons, surgeons to the police and fire departments in the larger cities, etc.

The Insurance Examiner.—There is a good field in this line for conscientious physicians; but unless a man be possessed of considerable patience and tact he will not be successful here. He must be able to gain the respect and confidence of the applicant for examination, he must remain on friendly terms with the agent, but he must at the same time not lose sight of the fact that upon the faithful and intelligent performance of his duties depends the protection of the interest of millions of beneficiaries. In appointing physicians the companies invariably give the preference to energetic, educated, tactful men, preferably those who have had hospital training or at least some experience. In the smaller towns where physicians are less numerous the same examiner may be in the employ of more than one company; the same condition also prevails in some of the larger cities. The remuneration varies according to the company. Some of the larger companies in New York City start their examiners on a salary of $1,000 per annum. He is expected to devote two hours daily in the Home Office, besides making two or three outdoor examinations. By systematically arranging his hours there is no reason why his private practice need be neglected. At the same time the physician is under no extra expense; he is brought in contact with people who may be favorably impressed, and he thus may possibly add to his private practice; and the fact that a large company has confidence in his ability carries with it a certain amount of prestige. Recently the larger companies have made a change in the matter of fees. Formerly the uniform fee for an examination was $5, but now the fee paid is graded according to the size of the policy which the applicant purposes taking out. When the amount of insurance is $3,000 or less the fee for examination is $3, and from this figure it rises up to $10 in proportion to the amount of insurance. The smaller companies and Fraternal Orders retain the uniform fee system, which is about $3 in each case whether the applicant is accepted or not, and without reference to the amount of insurance. The examiner may occasionally occur the displeasure of some rejected applicant or disappointed agent; therefore it is best when making an examination to avoid all controversies and unkind criticisms; bitter animosities lasting for years have sprung up in this manner. Most companies furnish the examiner with special forms upon which he may freely express his opinion as regards the applicant; and this information is treated confidentially by the company. The custom prevails in some of the larger companies to train a limited number of physicians in the Home Office for two or three months; these fully equipped examiners are then given important posts at distant points. The salary while in training is about $100 per month.

The Railway Surgeon.—The young physician wishing to enter the service of a railroad as one of its surgeons, had better cultivate the acquaintance of some railroad manager, prominent director, or chief surgeon. However, oftentimes his presence in time of need, and again merely a formal application by letter to the president, manager, or chief surgeon, stating his qualifications, may secure the appointment. As a rule the medical department of a railway is presided over by a surgeon-in-chief, who possesses the power to appoint assistants. These assistants assume responsibility of their divisions, and in turn have assistants who do the work and are known as company surgeons. Other leading railroads employ no chief surgeon, but simply appoint surgeons at different points along the line. Men of large experience always get the preference. A specialist is usually employed to examine the sight and hearing of all applicants for employment. It is the duty of the local surgeon to report at the scene of an accident as soon as notified; if he cannot go, he should send a substitute at once. Immediately after caring for the injured he should forward a report to the surgeon-in-chief, stating the nature of the injuries and the treatment adopted. A number of railroads arrange with hospitals along the line to receive their injured. In this line of work the salary is usually small, but the surgeon has an opportunity to increase his practice by obtaining patients in the families of the employees, and he has great advantages in surgical work. He and his immediate family are provided with a free pass over the road. Some railroads are supplied with a hospital car containing equipment for all emergencies. Owing to the great mass of humanity traveling in the day coaches and sleeping trains, the cars furnish an excellent nidus for the propagation of germs; and a fight should be made against the velvet upholstered seats and the draperies, particularly in the cars carrying the great number of tuberculous patients to northern New York, Colorado, and in the Florida specials.

The Police and Fire Departments.—The opportunities here are limited, as in this city not more than forty surgeons are allowed for the Police service at a salary of $3,000 per year, and only six for the Fire Department at $2,000 per year. The tenure of office is for life, unless discharged for neglect of duty. These positions are much sought after, and they come under the rules of the Civil Service, but the appointment is largely a matter of political influence. The amount of time required of the surgeon varies, but a fair average would be two or three hours a day. The physicians are expected to treat all uniformed officers of the force in their respective districts free of charge, but not their families. However, as they are often called upon to do so, and charge whatever they see fit for their

services, they add considerably to the income. While these positions are very desirable, it must be understood that they are practically not obtainable, in New York City, at least, by recent graduates in medicine, as the vacancies created are extremely few and the requirements are such that successful applicants are almost always men who have had considerable experience in the practice of medicine.

There is no more pleasant employment for the young man just after four years of hard work in college, or for the older practitioner, run down in health or tired of the uphill struggle, than a short term of service at sea. The travel and study of the many phases of human nature which are continuously presented must act as a great educator. The candidate for such a berth should secure if possible an introduction to the general manager of the company in which he wishes to serve. If this cannot be arranged, let him write a letter stating his qualifications, and then after a few days call personally to present his case. Persistence is the most important requisite; weekly visits to the general manager's office call that official's attention to the fact that the surgeon is awaiting an opportunity to serve the company. While waiting for an appointment the candidate should cultivate the acquaintance of the ship doctors; as a rule they are an affable set of men, and will give necessary information and advice. In this way he becomes conversant with the ways of the service, and may find an opportunity to substitute for one of the doctors. The candidate should be prepared to embark upon the shortest notice. The freight steamers, known as "tramps," are perhaps the most desirable for seeing the world, as they often visit several different countries. The Elder Dempster S. S. Co., with general offices at 21 Water Street, Liverpool, England, are the largest owners of steamships of this type. The ship doctor must be a graduate of a reputable medical college, and a man capable of conducting himself with dignity. It is compulsory on all vessels sailing between England and her colonies for the doctor to carry an English registry when the number of persons on board exceed one hundred. A few of the Transatlantic liners and most of the large ships sailing from New York to southern ports carry American physicians. The salary varies with the company, but may be said to range between $30.00 and $50.00, with a percentage on the sale of steerage tickets. Passengers requiring the services of the surgeon may compensate him as they see fit; on the large liners he may safely average between $50.00 and $200.00 a trip during the busy season. In the freight service the salary is from $20.00 to $35.00 per month. The doctor is supposed to pay for his laundry, also for his table and bedroom steward's services, likewise for wine and cigars. The ship doctor is at times called upon by the Captain to decide as to the advisability of placing one of the passengers or crew in confinement for misbehavior. The most careful judgment is necessary, as lawsuits may follow such proceedings. Again, it has been the duty of the ship doctor to have to order the captain to be subdued and restrained during an attack of mania. He should protect himself by procuring in writing the corroboration of the officers, crew, and passengers. In his treatment of the passengers he should exercise tact; in the event of an injury or the like, he can oftentimes procure a written statement from the patient expressing satisfaction with the treatment received; this statement will afterwards act as a deterrent when thoughts of securing legal redress occur to the patient. With regard to the steerage passengers, the doctor must vaccinate every one of them before they will be allowed to land. It is his duty also to examine each one of them as they board the ship so as to prevent epidemics, and he should also see to the sanitary conditions of their quarters. With regard to the crew, he is supposed to care for the sick and injured; but when a sailor becomes incapacitated for the proper performance of his duties through alcoholic or venereal excesses, it becomes his duty to report the matter to the company. The hospital facilities are necessarily very cramped; passengers are usually kept in their own berths. In time of need passengers may be transferred to passing steamers, or hospital supplies be obtained from them. The company demands a report from the ship surgeon of his work. On entering a port he must hand the quarantime officer a signed report on the health of the passengers and crew; and in the event of any deaths during the voyage he must report the same.

Finally, the recent graduate must remember that the necessity for work does not cease with graduation; he must keep in constant touch with the progress of his science. This is done in two ways, namely by the regular reading of a progressive medical journal and by occasional post-graduate study either in the larger cities of this country or abroad.

INFECTION WITH THE GAS BACILLUS—EMBOLISM AND THROMBOSIS IN THE MESENTERY—ETIOLOGICAL FACTORS OF GONORRHEAL ARTHRITIS—SURGERY AMONG THE CHINESE—SURGERY IN THE PHILIPPINES—THE BLOOD IN DENGUE—TROPICAL SPLENOMEGALY—DISCOVERY OF OPISTHORCHIS SINENSIS IN THE PHILIPPINES.

MANILA, P. I., March 2, 1906.

THE second session of the third annual meeting of the Philippine Islands Medical Association was held at 3 P. M. at the Bureau of Science.

The first paper read was entitled "Two Cases of Infection with a Gas-forming Bacillus, Followed by an Operation and Recovery," by R. C. Loving, M.D., Assistant Surgeon U. S. Army. This was a report of two cases infected with the gas bacillus of Welch, and probably these are the first cases that have been reported in the Philippine Islands. The laboratory work was done at the laboratory of the Army Division Hospital, by Assistant Surgeon Bloomburgh.

The next paper, entitled "Mesenteric Embolism and Thrombosis, with Report of a Case," by Major W. P. Kendall, Medical Department, U. S. Army. The interesting feature in this case was the fact that it was probably caused by traumatism. A soldier, age 21, well developed, apparently a healthy man, admitted to hospital May 21, 1905, 4:45 P. M.; family history negative. Two days before being admitted to the hospital he rode a bucking horse. While he was not thrown, he was badly shaken up. He was restless during the day, but suffered no marked pain, but during the night, twelve hours later, gradually grew worse. The pain localized itself in the right umbilical region. He did not apply for admission to the hospital until two days had elapsed. He complained of constipation, and bowels had not moved during preceding two days. Pulse, 88; respiration, 27; face wore an anxious expression. Physical examination disclosed rigidity of right rectus muscle, with tenderness about one inch inside of McBurney's point. Examination, however, was unsatisfactory, owing to tenderness. The case was operated on for appendicitis on the second day after admission. On opening the peritoneal sac a slightly blood-stained serum exuded, but no gas was noted. The coils of the intestines were apparently not matted together. The appendix was slightly congested and swollen. While it was not thought to be sufficiently in-

volved to account for the condition, yet it was amputated. Further examination revealed that the coats of the ileum were thickened, forming a tumor which rsembled an intussusception. The abdomen was then closed, but instead of improving the patient's condition grew worse, consequently, as a last resort, the abdomen was opened the next morning, through the original incision, and the tumor, together with the caput coli, about eighteen inches in all, were removed and the abdomen was then closed. Death followed, however, in twelve hours. Examination of the exected portions showed a tumor of the lower end of the ileum which was formed by all the coats of the gut; cylindrical in shape, well defined, mahogany color, and about seven inches in length. The mucous coat, over an area of about three inches, was found studded with small confluent ulcers, but showed no signs of perforation. The finding of an embolus was not reported.

The next paper was entitled "Etiological Factors of Gonorrheal Arthritis," by H. W. Smith, M.D., of the Medical Department of the U. S. Navy. The conclusions drawn by the paper were: (1) That vesiculitis is probably not often the focus of absorption from which arthritis arises. (2) Arthritis in the male is probably due to ulcers in the posterior urethra, from which systemic infection is made possible. (3) In the female, the failure of arthritis to develop when the infection is limited to the external genitals, makes it probable that in them absorption is over an area homologous to the deep urethra of the male. (4) Rarely, other sources must be allowed in both sexes.

The next paper was entitled "Surgery Among the Chinese," by Dr. Tee Han Kee. He stated that it was only the strictly Chinese art of surgery that he proposed to discuss, and he would not attempt to touch upon modern medicine and surgery. He said that the notions of the Chinese with regard to anatomy and physiology were absurd, and this was brought about by the fact that it was considered inhuman to open a dead body, or offer it up for dissection. He said it was believed that the heart was attached to the trachea, and contained more air than blood; that the lungs were believed to control the sense of smell. He said it would appear that they knew something of wound infection, though it was empirical; that even three thousand years ago surgeons always boiled their instruments and washed wounds only with boiled water. General and local anesthesia, according to the Chinese writings, was practised five thousand years ago. That operations were rarely performed, except the extraction of foreign substances from the body, the scraping of necrotic bones, and the puncturing of abscesses, although trephining of the skull had been done several times. He stated that diagnoses were made from inspection, as follows: The forehead represented the heart, and when it was red it indicated there was acute endocarditis; that the nose represented the spleen, and when it was yellow, malaria was present; the left cheek represented the liver, and when greenish, it indicated a diseased state of that organ; the right cheek represented the lungs, and when this was colorless, the person was said to have tuberculosis. The symptoms and signs of fractures given are practically the same as they are written to-day in modern text-books. For extracting a fish bone from the throat, the saliva of a dog was used, which had been taken while the dog was hung upside down, the theory being that, dogs being able to digest bones, it was thought that the saliva had a beneficial effect. When a patient was found with a snake coiled around his body, with no tendency to loosen, the patient was advised to roll on the ground until the snake became tired and loosened itself. For hemorrhages, the wound was usually tamponed with tobacco or cauterized with hot irons; in perforations of the abdominal walls the wound was washed with boiled vinegar. He concluded his paper by stating that Chinese surgery was empirical and superstitious, and not at all scientific, but that a gradual change was taking place, and he believed that in a few years China would be one of the centers for scientific research.

The next paper was by Dr. John R. McDill, on "Observations on Surgical Diseases, and Surgery in the Philippines." Dr. McDill stated that the observations made in his paper were principally based upon his experiences of the past year at the Saint Paul's Hospital which had given more opportunities for observing some of the major surgical diseases among the Filipinos than had heretofore been the case. The number of cases of cancer coming under observation was much larger than generally supposed, although scirrhus of the breast was apparently very rare. It was also rare to find hernias among Filipinos. He stated, as a rule the native stood surgical operations very well, taking anesthetics without trouble, and rarely ever suffering from shock. He attributed this favorable condition to their abstemiousness. He gave, in detail, his favorite method of entering the abdominal cavity for liver abscess. He stated that a sufficient portion of the lower ribs on the mid auxiliary line were resected, to give free access to the liver, and stated that, although the danger of collapse of the lung was to be feared, yet, if the operation was carefully done, it is not a very serious matter.

The next paper, entitled "A Study of the Blood in Dengue Fever, with Particular Reference to the Differential Count of the Leucocytes, and the Diagnosis of this Disease," was read by Dr. E. R. Stitt, Surgeon, U. S. Navy. He stated with regard to the micrococcus being the cause of dengue, as claimed by two investigators, in 1885 and 1897, that he was unable to give any evidence. The matter, however, had been investigated by the Bureau of Government Laboratories in the Philippines, in 1902, with negative results. The claims of Dr. Eberle, made in 1904, that he found in dengue a plasmebic organism which was more minute and more active than the malaria parasite, he did not consider well founded. The fact that he claimed the most satisfactory results in staining with weak eosin and methylene blue, would indicate that with thin preparations its discovery should be of little difficulty. The statement that he found phagocytes literally swarming with the minute organisms of dengue, and from an examination of his diagrams, leads Dr. Stitt to question whether he might not have been observing an aggregation of blood platelets. Dr. Stitt stated that in many of the films stained by him by Wright's method, he observed masses of blood platelets, from which such diagrams could have been made. Dr. Stitt was of the opinion that the most characteristic blood findings of dengue are the following (1) Absence of protozoa; (2) leucopenia; (3) diminution of the polymorphonuclears; (4) a striking variation in the percentage of other leucocytes at various periods of the disease, there being at first a great increase in the small lymphocytes, and then a greater proportion of large lymphocytes, and in the final stages, at the time of the terminal rash, and during convalescence, a most striking increase in the mononuclears.

The next paper was on "Tropical Febrile Splenomegaly," by Dr. P. G. Woolley, Director of the Serum Laboratory of the Bureau of Science. He stated that tropical splenomegaly was characterized chiefly by splenic hypertrophy, emaciation, irregular temperature which is uninfluenced by quinine, and certain intestinal symptoms as diarrhea or dysentery, without the presence of amebas. Such cases have been reported from various parts of India, Egypt, China, Tunis, Algiers, Arabia, and the Philippine Islands. He stated the peculiar parasite had been described first by Leishman, in a case at Dum Dum, in India, and later by other investigators. The parasites, when present, were found in large numbers, and are usually obtained by puncture of the spleen, and in fresh preparations are difficult to distinguish, but they may be differentiated from bacilli by their greater refraction. They are best stained by the Romanowsky method, are usually circular or oval in form, often have a cockleshell appearance, and usually show chromatin masses, the larger ones staining faintly and the smaller ones taking an intense stain. They have also been observed in the liver, mesenteric lymph glands, bone marrow, kidneys, and the skin lesions of the disease known as oriental sore. Dr. Woolley reported a case, and stated it occurred at the Saint Paul's Hospital, and that the patient died after a month's illness. The organisms found, both ante-mortem and post-mortem, were small bacilli. A culture was injected into a monkey, with negative results. In conclusion, the author stated that after studying seven cases he was of the opinion that the infection must be due to the Leishman body, but that it would be necessary to search for further etiological data before we could understand and satisfactorily classify the whole group of cases as characterized by the gross features of kala azar.

The last paper read was entitled "The Occurrence of *Opisthorchis sinensis* in the Philippine Islands, with a Demonstration of the Parasite," by Dr. Wm. J. Mallory, the Physician in Charge of the Benguet Sanitarium. The parasite was discovered by Dr. R. P. Strong, in some material forwarded by Dr. Mallory, and is believed to be the first time that *Opisthorchis sinensis* has been reported in the Philippine Islands. The case occurred in a Japanese laborer who was working on the Benguet road, who applied for treatment at the sanatorium. He also had crescent forms of malaria in the blood, and uncinaria in the feces. After a short course of thymol and quinine the uncinaria and malaria disappeared, but *Opisthorchis sinesis* was still present at the time the man left the hospital.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COLLEGE OF SURGEONS—PRIZE FOR CANCER RESEARCH AND OTHER PRIZES—DOCTORS AND THE DAIRY INDUSTRY—*x*-RAYS IN SARCOMA—GASTROJEJUNOSTOMY—CONSUMPTION HOSPITALS.

London, April 6, 1906.

Yesterday at the meeting of the Council of the Royal College of Surgeons the Walker Prize of £100, founded by the late Mr. Charles C. Walker, to encourage investigation into

the pathology and therapeutics of cancer, was awarded to Professor Carl O. Jensen of Copenhagen. The advisory committee's report to the council acknowledges assistance from foreign and British surgeons and pathologists and remarks that much important work could not be considered, as it was not done within the time limit, had no direct bearing on treatment, or was not finished, though that under the last head may be perhaps under consideration at the next award. In recommending that Prof. Jensen should receive the prize on this occasion the committee cite a description of his work by Prof. Salomonsen of the State Serum Institute of Copenhagen, as follows:

"The inoculation of cancer from animal to animal had been made in comparatively few cases, and therefore afforded no decisive material for the study of cancer. Prof. Jensen first succeeded in discovering a tumor in the mouse, which made the experimental investigation of cancer on a large scale possible. Prof. Jensen first carried out a large series of inoculations through thirty-five generations, comprehending about 1,000 mice, and thus gave the impulse to certain experimental investigations which are now carried out in many laboratories in different parts of the world. He thus made it possible to investigate, and was himself the first person to investigate systematically the effect of different factors (heat, light, chemical agents, radium, etc.) on the cancer cells. He further demonstrated the possibility of producing an anti-cancer serum for mice by the injection of the crushed tumor into rabbits. The serum of rabbits which has been thus prepared has been injected into mice suffering from cancer, with the result that the cancer tumors in many of them have disappeared absolutely and permanently."

The report further states that in proposing Prof. Jensen for the prize the committee were influenced not merely by the work he has himself done, but also by the extent to which he has opened up a field of research to all engaged in the study of cancer on certain lines, enabling them to carry out their investigations over long periods and under better conditions than have heretofore been possible.

Other prizes and honors were awarded at the same meeting yesterday, viz., the Jacksonian Prize for 1905 to Mr. Reginald C. Elmslie, M.S., F.R.C.S., and the first Begley Studentship to Mr. W. B. Johnson. The Honorary Medal of the College was awarded to Lt.-Col. Sir Richard Havelock Charles, in recognition of his gift of anthropological specimens, an addition of special value to the museum not only for the number and variety of the specimens but also on account of the authentic particulars attached to them.

Dr. Lucas Championière of Paris was elected an Honorary Fellow.

Surg.-Gen. A. M. Branfoot, C.I.E., of the India Medical Board, and Mr. H. M. Ellis, R.N., director general of the Navy Medical Department, were elected Fellows as members of twenty years' standing.

On Monday Mr. J. L. Lloyd lectured on "The Relation of the Profession to the Dairy Industry." Protesting that many, nay most, microbes were not at all injurious, he held that the older statements of bacteriologists had been shown to be wrong. He declared it had not been proved that the tuberculous disease of cows was communicable to man, and then he proceeded to give as one instance of medical fallacies the statement in a recent lecture by Dr. Thresh, the eminent M. O. H., that "from 20,000 to 30,000 infants perished annually in the United Kingdom from diarrhea, a large proportion of them being infected through the milk." This view, Mr. Lloyd declared, had probably less evidence in its support than any other concerning milk. When pure the liquid had an antiseptic action internally; when sour it might cause diarrhea and should not be given to infants unless it could be heated without curdling. Fear of disease germs led doctors to sterilizing milk, which made it less digestible and less nutritious, while it often failed to destroy the spore-forming bodies, and these having the field to themselves when the lactic acid organisms were killed produced toxic compounds. He had known several cases of poisoning by sterilized milk which had been kept too long. Milk should be drunk in a natural state.

At the conclusion of this lecture, up rose Dr. Thresh himself to offer a few criticisms. He said the presence of a great number of microbes was a sign of impurity, although Mr. Lloyd thought them of so little importance. Toxins, said Mr. Lloyd, and not bacteria might cause illness. But what were toxins? They were the products of microbes. If bovine tuberculosis could not be transmitted in cow's milk, how was it that the tubercle bacilli found in the intestines of children were so often of the bovine species? Mr Lloyd denounced him for saying diarrhea in young children was often due to milk, and in the same breath admitted it might be caused by sour milk. But sourness was produced by microbes. Nobody denied the value of pure milk in a natural state. If it could always be obtained doctors would recommend no other.

Dr. Busch showed at the Clinical Society a man of 37 who contracted syphilis in 1896 and had since been treated vigorously. In September, 1904, he had swelling and cyanosis of face and neck, the right half of the thorax was painful at night, and swallowing became difficult. A swelling appeared on the second and third sternocostal joints and another in the right supraclavicular space. Iodide was given, but the patient got worse. In February, 1905, he went to Vienna, where *x*-rays were employed and improvement occurred. A gland removed from the supraclavicular space was sarcomatous. He has since gained weight and lost all pain. Some similar cases were mentioned.

Mr. W. G. Spencer remarked that treatment by the rays would only be waste of time in some sarcomata; but in others, those called in this country lymph adenomata, it might be successful. These, however, had been known to disappear under iodide and arsenic long before Roentgen's discovery.

Mr. Wallis has communicated three cases of gastrojejunostomy which have points of interest. The first was in a woman aged 91, who made an excellent recovery, losing all the symptoms. She died twelve months later from cerebral thrombosis. A speaker who had seen the case said he had been much impressed by the relief experienced and thought old age in itself was not a bar to serious operations. The two other cases were instances of chronic inflammatory thickening around an ulcer, simulating a new growth. In both a posterior gastrojejunostomy was done. In one when, a month later, the abdomen was opened to do a partial gastrectomy, the supposed growth had disappeared almost entirely and the patient has recovered. In the other the patient died on the fourth day from hemorrhage, and the autopsy revealed a large ulcer with a vessel along its floor having an opening about the middle. Mr. Wallis thinks these two cases show that a posterior gastrojejunostomy should precede gastrectomy, and if there has been much hematemesis the stomach should be opened through healthy tissue in the neighborhood of the ulcer, which can then be cut out, cauterized, or ligatured to prevent further hemorrhage.

The proposal that the Asylums Board should undertake the establishment of sanatoria for consumption has not received the sanction of the Local Government Board, which has replied to the application that the "information at present before them does not appear to afford sufficient justification for the very heavy outlay which would be involved." Sir W. Broadbent now says the Asylums Board is too closely associated with poor law administration to be suitable, but that there are other agencies in existence, all that is needed being to combine and direct their efforts. He also says "a great deal could be done at very little expense," on which last point most people will differ.

Some provisional figures were issued on Tuesday which will probably differ slightly from the revised statistics to be presented in the Registrar General's Report. The marriages in England and Wales in 1905 numbered 260,489; the births, 929,457; the deaths, 519,939. The estimated population at the middle of the year is put at 34,152,977.

The Maida Vale Hospital for Epilepsy and Nervous Diseases has been fortunate enough to get its assessment reduced from £570 to less than £100. Even with that it is in want of help, for its expenditure is about £3,000 and its ordinary income, including grants from the three funds, was only £1,087 last year; 166 in-patients were treated in the twenty-nine beds, the average period of residence being seventy-five days.

The Governors of the Queen's Jubilee Hospital, which you know chiefly from complaints of its mismanagement and its not being required, determined on Tuesday to change its name to the Kensington General Hospital. By any other name it will smell as sweet. A speaker said it had been subjected to a starvation process, only £181 having been subscribed last year, though £2,000 was sent from its neighborhood to the King's fund. Surely this only shows that the public endorses the verdict of the profession.

OUR COPENHAGEN LETTER.

(From Our Special Correspondent.)

THE NUMBER OF LEUCOCYTES—A NEW TREATMENT FOR HEART DISEASES—THE FINSEN MONUMENT—THE FIRST DANISH LADY M.D.—OBITUARY NOTE.

COPENHAGEN, March 17, 1906.

THE last few months have witnessed the publication of two noteworthy medical investigations by Danish writers, thus giving an eloquent evidence of the assiduous scientific work carried out by the profession in our little country. The number of leucocytes in normal blood has been inquired into by Dr. Kjer-Petersen, who reduces *ad absurdum* in a vehement, but as it seems justified, onslaught most of the researches made before him in this line. The writer points out that most of the prior investigations have been carried

out without ascertaining the exact size of the error which necessarily adheres to the method of examination. This fault cannot be determined once for all, but anybody working with the counting of blood corpuscles must as a preliminary make out for himself how great the error is in his particular case. Otherwise he does not know what to believe of the numbers resulting from his counting. This may appear obvious, but in reality it is astonishing to see how many investigators count away without having the slightest idea of the exact value of their results. Taking due regard to the mentioned error, Dr. Kjer-Petersen has counted the leucocytes in the blood of a great many normal persons and is able to determine the number to be from 4,000 to 5,000 in each cubic centimeter of blood taken from men just after their awakening in the morning. This number remains unaltered day after day for a very long time. On the other hand, the examination of healthy women had the very interesting result that the number varied greatly (from 3,000 to 24,000), and not only in different individuals, but very considerable variations might occur even in the same person. The blood of women is therefore called inhomogeneous by the writer, while he considers the blood of men as homogeneous. It will easily be seen how important the knowledge of the normal variability of the number of leucocytes in women may be, for example, to the surgeon, as of late years one of the indications for operating in cases of appendicitis has been sought in an increase of the number of leucocytes. Of great biological interest is the writer's statement of the great difference between men and women as to the number of leucocytes, and it is much to be desired that the correctness of it be tried by other investigators. But anybody wishing to inquire into this matter must of course also be prepared to work with the same painstaking exactness as the author.

Besides having a great biological interest, the last-mentioned statement of Dr. Kjer-Petersen may perhaps be of considerable social importance. At least, I should not be astonished if it proved to be a new and useful weapon in the standing contest, whether man or woman is to be considered as the superior being. Without doubt, both sides may take advantage of it.

A certain sensation has been caused by a publication by Dr. Hasselbalch, director of the laboratory of the Finsen Light Institute. Dr. Hasselbalch has made researches as to the effects on circulation and respiration produced by electric light baths. Now several writers have enriched our knowledge of the *immediate* effects caused by and observed during such baths. But the novelty in Dr. Hasselbalch's investigations is that he has determined the *lasting* results of the exposition of the naked body to a strong electric light. By means of exact methods he has succeeded in proving that the hyperemia of the skin produced by the light-bath is accompanied by a considerable diminution in the rate of respiration, and that this decrease may persist for many days after the bath. Another and yet more important fact is that the average blood-pressure in the brachial artery decreases to the amount of 8 per cent. after the light treatment. This diminution of the blood-pressure has a fixed minimum value for a given light source, below which the pressure does not sink, although the light treatment be continued. The decrease of the arterial pressure is caused by dilatation of the peripheral vessels and may persist more than a month after the light-baths are discontinued. It will easily be seen that these results of the light treatment, if constant, may be of great importance for the treatment of heart diseases. A diminution of the blood-pressure, produced by a dilatation of the peripheral vessels, has the effect that the work required of the heart also becomes lessened, and that the area of heart dullness is diminished. In other words, we have here a therapeutic agent that works in the same way as the carbonic acid bath (Nauheim cure), but with the valuable difference that it is followed by a far more pronounced and lasting dilatation of the peripheral vessels. Dr. Hasselbalch's investigations may mark the beginning of a new era for the Finsen Institute and certainly deserve attention from the medical public. Several patients suffering from diseases of the circulatory system have already been treated at the institute, with good results, and it is intended to add a new department for light-baths, in order that the Finsen Institute of Copenhagen may continue to be at the lead also in this line of light treatment.

Of course new, fruitful applications of the therapeutic powers of light form the most appropriate monument for a man like the late Professor Finsen. Perhaps they will also be the only one that he will get. This remark is caused by the edifying contest going on between the Danish sculptors and the so-called Finsen Committee. It is perhaps remembered that an international subscription was opened after the death of Finsen, with the object of erecting a monument for him, and the very pretty sum of $25,000 to $30,000 was contributed, from practically all parts of the civilized world. In the meantime, however, the Danish Finsen Committee, presided over by the Prime Minister, has decided that only a part of the total sum, to the amount of $7,000 to $9,000, be expended on the monument, the rest of the sum going to make up for some deficits in the balance of the institute, caused amongst others by the proposed new buildings. The Danish sculptors have answered this decision of the committee by declaring that none of them is willing to take over the job of erecting a monument worthy of a man like Finsen for the paltry remuneration proposed. So that the committee will have to be satisfied with some ready-made monument in the pastry-cook style, or increase the amount to be paid for a monument.

The latest piece of medical news is that at length we have now got our first lady M.D. Since 1885 women have been admitted to pass the final medical examination and to practise in Denmark. But it is not here as in the United States that one becomes an M.D. before obtaining a license to practise. The Danish degree of M.D. may most appropriately be compared to the German one of *habilitation*, because in both cases the publication of an original scientific work is a necessary condition to the securing of the degree. Another similarity between the Danish doctorate and the German *habilitation* is that both of them give a right to become *Privatdocent, i.e.* to lecture at the University. As mentioned, the degree has at last been conferred upon a lady colleague with due honors, and the result has been exultations innumerable in the papers devoted to the cause of the fair sex.

I regret to record the death of Professor Wanscher, a prominent man and of a most captivating character. To the world at large he was perhaps best known as the originator of a simple and efficient apparatus for etherization, which method of narcotizing he always strongly recommended.

YELLOW FEVER CONTRACTED DURING THE DAYTIME.

To the Editor of the Medical Record:

Sir:—Referring to the exposé, in your editorial of March 17, "The Older Views of Yellow Fever," of the doctrine that this disease was not contracted during the day, the following observation may be of interest:

After considerable yellow fever in Panama in the early part of 1905 there was no case reported from March 23 to April 21, during which time, then, there could not have been much in the city. From that time to May 6 eighteen cases were reported, all, save one, Americans, fourteen of whom worked in the Administration Building. The other three Americans, while living elsewhere, were in the Administration Building on business within the limits of their incubation. It is not recorded whether the other patient—an Italian—was in this building or not. The Americans were easy to trace. They lodged in numerous boarding houses and hotels in almost all parts of the city, and some in places outside of the city, at Ancon, Corozal, and Empire. No case of yellow fever developed at or near this time in these houses or towns except among those who worked in or visited the Administration Building. Some cases developed, as in the Chief Engineer's house, the Section, and in the grounds of Ancon Hospital, in places where no other case ever developed since the Americans have been here. This outbreak was followed in a short time by a spread of fever in many parts of the city. The evidence seems convincing that the source of infection was the Administration Building. This is an office building, the hours being from 8 A. M. to 5 P. M. I do not mean to say that none of those who developed the fever ever stayed after 5 P. M.; some, doubtless, did, but this practice was not general, and among those who developed fever in this outbreak, those living out of town were certainly in the building only during office hours. At this time, the latter part of April, the sun sets well after 6 P. M. These cases, then, if contracted in the Administration Building, *were contracted during the day.*

It is unquestionably true (as you quote) that it has been (but I think not since 1888) very generally accepted that yellow fever is never contracted during the day "when the sun is well above the horizon"—as generally accepted as was the transmission by clothing. To be generally accepted, however, is not to be proven, and the evidence for this belief, since it seems still to exist in the United States and has the endorsement of the Pasteur Commission which went to Rio, should be investigated. Of the conditions at Rio and Petropolis, always quoted in this connection, I have no personal knowledge; nor of the instances occurring prior to 1888 of "daylight communication" alleged to show that yellow fever cannot be contracted in the daytime; but for yellow fever, as it has occurred in the United States since 1887, and as we have observed it in Cuba and Panama, the evidence is decidedly against this doctrine.

We know that *Stegomyia fasciata* habitually bites most in the afternoon, here from 3 o'clock on, but I have seen them feeding in a moderately dark room—my office—as early as 2 P. M., and at 1 P. M. in a darker room. They also feed at night, 7 to 8 P. M. by lamp light, but in my experience very sparsely. I *think* they do not feed in the dark without artificial light, but I do not *know* this. I have not found them, or have found them with extreme rarity, under our bars in the morning, while *Culex* and *Anopheles* were so found continually. Up to May, 1904—since which time I have had little opportunity to read—there was no *direct* evidence that this variety (*Stegomyia fasciata*) fed at night in the dark, or that there was any difference in the habits of feeding between the newly born and the two-weeks old females, whether the latter be infective for yellow fever or not. The Pasteur Commission at Rio (Marchoux, Salemleni, and Simon), drew the *deduction* that the old—and all infection for yellow fever must be old mosquitos—mosquito fed by preference at night. This was based on their acceptance that yellow fever was not contracted during the day. There was no direct observation on the feeeding of mosquitos to confirm it. They said "by preference" because they knew that the experimental cases of Reed, Carroll, Guiteras, and others were produced by infective mosquitos feeding on the subject during the day. These mosquitos, however, were in confinement and not altogether under natural conditions, and could exercise no preference about feeding—must feed when they had a chance. I have not had access to the reports of the Pasteur Commission for about two years, but think that I quote them, in substance, correctly.

My opinion, based both on observation of the disease and on the habits of *Stegomyia fasciata*, is: (1) No time of the twenty-four hours is always safe in infected houses; (2) the forenoon and early afternoon, the rooms being bright and sunny, is the safest time, and the later afternoon the least safe. From the habits of *Stegomyia fasciata* I would also deduce that the sleeping hours at night are fairly, or very, safe, but I know of no observation of the disease itself bearing this out, nor indeed any to the contrary.

H. R. Carter, M.D.,
Surgeon, P. H. and M. H. S. and
Director of Hospitals, I. C. C.

Ancon, C. Z.

Progress of Medical Science.

New York Medical Journal, April 14, 1906.

Intraperitoneal Shortening of the Round Ligaments.—This procedure is considered by J. M. Baldy in its application for the relief of backward displacements of the uterus. After some remarks on the function of these ligaments, the results following their relaxation and operative methods in vogue, he passes to the special method frequently known by his name. The technic is as follows: The broad ligaments are perforated from their posterior surface by forceps, which on emerging on the anterior surface are made to grasp the round ligaments, which are then drawn through to the posterior surface with the forceps. The round ligaments are brought together and sutured both together and to the uterus low down on its posterior surface (at about the position of the internal os). This accomplishes three things: (1) The tilting forward of the uterus to a normal anterior position. (2) The lifting up of the whole pelvic floor from its sagging position. (3) The uplifting and support of the ovaries and tubes. The three results are of necessity a part of each other, and one is as constant as the other. The most important of all, the uplifting and support of the ovaries, is absolute and sure; and this result is accomplished without the slightest pressure on these delicate organs. The author considers this method the best one with which he is acquainted, as it allows of the treatment of complications through one single incision. It has none of the uncertainties of result that obtain in the suspension operation (complete failure to suspend or overstretching of the band) and none of the dangers of the fixation. It is rational in that it gives a fairly sure substitute for the lost elements of support and does absolutely no harm. It allows of pregnancy in any woman who could in any event become pregnant.

The Aims and Limitations of Intranasal Surgery in the Treatment of Chronic Nonsuppurative Affections of the Middle Ear.—T. J. Harris refers to the changes of opinion of the last sixteen years with reference to the relation of intranasal lesions to ear disease. He believes that it is no longer possible to draw the old conventional lines of demarkation between the two specialties of rhinology and otology. Such a tendency to amalgamation should be recognized in our teaching and in our clinical work. He recapitulates his opinions on the following propositions: (1) The nose plays an important rôle as a causative factor in many cases of otitis media, but by no means in all cases. (2) The lesion in the nose is usually of an obstructive nature, acting as an obstacle to proper ventilation of the middle ear. (3) In beginning cases of hypertrophic otitis media a certain amount of improvement in the hearing can be confidently expected by restoring proper ventilation of that cavity through measures addressed to the nose, with the aim of relieving nasopharyngeal and tubal inflammation; yet only such cases of the disease call for nasal treatment as show pathological changes in the throat themselves demanding attention apart from the condition of the ear; it is important to determine the true nature of the process in the middle ear, as the sclerotic or so-called hyperplastic form is not influenced at all by such treatment; adhesive changes and ankyloses cannot be expected to yield, however completely the nasal obstruction is removed. In a word, while suitable cases are capable of being helped, many cases of chronic otitis media associated with certain nasal obstructions do not call for and will not be improved by any form of nasal treatment, and all such treatment in these cases is unjustifiable and unwarranted. (4) An important result to be secured by treatment is the relief afforded from the repeated attacks of acute rhinitis which by their effects on the Eustachian tube are wont to aggravate the chroic condition. (5) Tinnitus aurium and vertigo are at times benefited by nasal treatment. (6) Finally, because of the importance of treatment to the nose and throat a closer association clinically of otology and rhinology is urgently demanded.

The Influence of Certain Antipyretics on Nitrogen Metabolism.—A series of experiments has been made by H. Morgenbesser upon persons with a purinfree diet made up of milk, cream, eggs, sugar, and water. At the same time certain drugs were given and their results on nitrogen metabolism calculated according to methods given in full in the paper. It was found that sodium salicylate increased the total nitrogenous output, increased urea, and ammonia, while uric acid and xanthin bases were not increased. Quinine decreased the total nitrogen, the urea, uric acid, total purin bases, and slightly increased the ammonia elimination. The nitrogen decrease began at once and stopped immediately on the discontinuance of the drug. It seemed to stimulate the organism to make up for this decrease. Acetanilid increased the total introgen, urea, uric acid, and greatly the ammonia.

Journal of the American Medical Association, April 21, 1906.

Malaria on the Isthmus.—A. I. Kendall sums up the result of his study as follows: At the time of the investigation of the towns examined, fully 50 per cent. of the natives and 75 per cent. of the foreign-born inhabitants had malarial parasites in their peripheral circulation. This, however, does not mean that all patients presented febrile symptoms, as many of them did not. This high percentage, nevertheless, is a serious menace to the health of those who for any reason are compelled to stay in these towns, especially on account of the prevalence of *Anopheles albipes*, a mosquito shown to be a carrier of malarial infection. Other species may also be factors to a less extent. The estivoautumnal type is the prevalent one; Chagres fever is probably only a severe estivoautumnal infection. Pernicious malaria is not caused by a distinct parasite, but by an estivoautumnal organism of exalted virulence. Natives and their descendants or, generally the descendants of those who have resided for many years on the Isthmus, have at birth, to a certain degree, an inherited immunity. An active immunity, which is by no means absolute, is generally acquired, becoming manifest about the age of 16. The foreign-born individual acquires a certain tolerance, but not so great or so early manifested as that of the native. Malaria is an environmental disease; occupation has very little to do in its causation. Quinine in moderate daily doses, while it does not insure against the disorder absolutely, nor completely drive out the malarial organisms from the circulation, has an important prophylactic and curative effect.

Ileosigmoidostomy for Intestinal Ulcers.—R. C. Coffey reports a case of the successful utilization of the operation of ileosigmoidostomy for this condition. The patient, a man aged 22, had suffered for years from obstinate constipation with great distention of the bowels and disabling pain, for which he had not been able to obtain relief. The pain was localized at the splenic flexure, and the patient thought that there

must be an obstruction at that point. An exploratory operation revealed a distended and congested colon, but no evidence of obstruction. The appendix was not seriously diseased, but was removed as a possible source of irritation. No relief was obtained, and three weeks after this exploratory incision, the patient demanded another operation. In this the ileum was cut in two, between clamps near the ileocecal valve, the two ends were turned in, and an ileosigmoidostomy was performed. An indurated ulcer was found about two inches above the point of anastomosis, and another about three inches higher on the descending colon, near the mesentery. Another probably existed near the splenic flexure, which could not be explored through the wound. The patient made a perfect recovery. Coffey thinks the operation will have a considerable value in diseases of the colon in which rest or drainage are required. In his case the bowel functions seem to be perfectly normal and there is no disturbance of digestion.

Some Points in Anesthesia.—R. H. M. Dawbarn offers several suggestions regarding major anesthesia. In case ethyl chloride is used as the beginning of ether anesthesia, and the Clover air bag is employed, he advises putting into the bag two of the 10 c.c. tubes of ethyl chloride with easily broken, drawn out tips, wrapping them in a gauze sponge secured by an elastic band, and then, with the face piece in position, breaking the tip of one through the rubber bag. If this is done, the anesthesia is commenced without any such waste as would follow first breaking the tube and dropping it into the bag. Usually it will not be necessary to break the second tube. He believes the rebreathed, lung-warmed ether in the Clover air bag is much less likely to cause ether pneumonia, besides being much more economical. The second point emphasized is the hanging up near lighted lamps or gas jets, when chloroform has to be used, of cloths wet with ammonia. The resultant chemical affinity produces ammonium chloride and prevents the irritation from the freed chlorine. The third point refers to the administration of an anesthetic during natural sleep. Dr. Dawbarn advises, in case of a child, selecting the usual hour for its daily sleep, entering the room noiselessly, and administering the anesthetic cautiously. The fourth point mentioned is regarding the common advice to remove all artificial tooth plates. He thinks that there are some exceptions to this rule: When the plate is large and the pharynx of only ordinary size, swallowing or choking with the plate in position is out of the question, while if it is removed the cheeks and lips may fall in so as to interfere with the breathing space, especially if there is coexisting nasal obstruction.

Accuracy in Dietetics.—Dudley Roberts remarks on the common neglect of accurate regulation of the diet by the physician and accounts for it by assuming that the matter has never been presented in practicable form. Food weighing is out of the question in ordinary practice, and the directions should cover what is actually eaten, not what is served, or serious mistakes will be made. He, therefore, presents a table giving the actual quantities in the ordinary household measures, and the number of calories and grams of proteid contents to each measured spoonful, glass or dish of the different foods as offered for consumption, with such additional remarks in each case as seems needed. For patients requiring accurate regulation of diet, this table will come into play and will also enable the physician to calculate with reasonable accuracy the amount of nutrition that has been taken and to note the facts in connection with the symptoms observed.

Glandular Fever.—H. Schiller reports six cases in addition to the five before published by him under the title of "Pfeiffer's Glandular Fever." These cases, he states, do not correspond exactly with the cases described by Pfeiffer. The cases Schiller reports are well characterized; the most striking symptom is the sudden swelling of certain glands in the neck, not usually painful or tender. One patient had chills, headache, pains in the abdomen and back, and some vomiting. In all cases there was some pain in the throat, but not so severe as in ordinary tonsilitis. Three of the patients had acute hemorrhagic nephritis as a sequel, as severe as that following scarlatina. The spleen and liver were somewhat enlarged in all cases, and the long duration of the swelling and slow absorption were characteristic. Suppuration occurred in three cases. In one case influenza bacilli were found alone, in another streptococci alone and both together in a third. The disease had the characteristics of an infectious fever, with suggestion of contagion in some cases. The prognosis was good in all.

The Lancet, April 7, 1906.

Doyen's Serum in Malignant Disease.—A. Paine and D. J. Morgan review Doyen's theories as to the occurrence of his so-called *"Micrococcus neoformans"* in malignant growths, and the various steps leading up to the elaboration of his serum. Of nine cases treated by them with serum injections, no effect on the course of the disease was noted in four. In two, the injections were followed by severe pains, and in three by severe constitutional disturbances. Concerning the *Micrococcus neoformans,* the authors note that it is often present with other micrococci in malignant tumors, but in their opinion not in sufficient numbers or with a constancy to enable it to be regarded as the etiological factor in the evolution of these growths. In their hands the inoculation of animals with this organism has been followed not by the formation of neoplasms, but by the expression of inflammatory reactions.

The Pathology of Gangrene and Perforation of the Hollow Abdominal Viscera and "Acute Perforating Ulcer of the Stomach."—D. Drummond and R. Morison discuss the question of patchy gangrene followed by perforation, with special reference to its occurrence in the gall-bladder, appendix, cecum, urinary bladder, and stomach. In all the cases to which they refer, the lesion commences as a small patch, more or less circular in outline and at that portion of the wall of the viscus farthest from the source of its vascular supply. With reference to the stomach, their view is that excess of hydrochloric acid in the stomach, by producing pyloric spasm and acute gastric distention in an anemic girl, gives rise to a small gangrenous patch or patches in the stomach wall, and that subsequent digestion of the dead or devitalized patch, if all the coats are involved, leads to perforation. It is generally recognized that the stomach juices in certain circumstances destroy its own wall. They add that a sudden attack of distention due to pyloric spasm in the case of a chronic ulcer probably accounts for perforation in many instances.

The Treatment of Cancer by Therapeutic Inoculations of a Bacterial Vaccine.—The experiments made by C. Jacobs and V. Geets as controlled by measurements of the opsonic powers of the blood convince them (1) that there exists in cancerous cachexia a specific microorganism, the *Micrococcus neoformans* of Doyen, (2) that the Doyen sera with which they have experimented are wholly useless, and (3) that it is practicable to minimize the human organism by means of a series of inoculations of the *Micrococcus neoformans* vaccine under the control above mentioned. They describe their methods of preparation and employment of this vaccine. They summarize their results in 46 cases as follows: "Cure," maintained after several months, 7; lasting improvement, 12; transient result, 7; no result, 12; still under treatment, 9. Detailed histories are given of five cases. They believe that in certain cases the vaccine can do much, but in others nothing. Just as a tubercle vaccine judiciously administered does not cure all tuberculous cases, so a cancer vaccine cannot cure all cancer cases. The question of success or failure in cases apparently alike turns on such factors as reserve of vital energy and the capacity for reaction which each patient possesses, and this differs in each case. With regard to the immunizing they can express a definite prognosis after two or three injections of the vaccine, the alterations effected in the quantity of the opsonins expressing accurately the strength of the autoprotective reaction. For example, when the opsonic index does not rise after one or two injections the case is irremediably lost, the immunity has fallen to the lowest degree, the defensive powers seem exhausted and cannot be stimulated by anything. Continued injections in such cases can only hasten the death of the patient, since each injection of the vaccine removes a certain amount of the protective substances, and as no phase of manufacture, no positive phase, succeeds to this, there is merely set up dangerous cumulation of negative phases, leading the patient to an early death.

British Medical Journal, April 7, 1906.

The Effect of Various Rays on Trypanosomes.—R. Ross states that he has exposed liquid preparations of blood containing numerous active trypanosomes, for periods varying from half an hour to one hour, to very strong rays of the Roentgen, Finsen, and radium varieties. No appreciable effect whatever was produced on the activity of the organisms.

Freezing Tissues for Sectioning.—A. F. Stanley Kent commends the use of carbon dioxide for this purpose. He connects the cylinder of compressed gas (which is kept in the upright position) by means of rubber tubing

with the ordinary ether-spray apparatus. The pressure from the cylinder takes the place of the pressure from the bellows, and there is a slight additional cooling effect produced by the expansion of the gas. Ether is employed as usual, but the freezing is accomplished so quickly that the extra expense may be disregarded. The advantages of the method are its perfect simplicity and great convenience. Tissues can be frozen in a couple of minutes and kept at any desired degree of hardness for as long as necessary by simply altering the valve on the cylinder. One caution is necessary: the rubber tube should be loosely connected with the cylinder—that is, should not be tied on, so that it may act the part of a safety valve, and may be blown off in the event of too sudden an opening of the cylinder cap.

The Value of Sarsaparilla in Syphilis.—A series of cases of syphilis is summarized by C. J. Cullingworth, who administered a decoction of sarsaparilla to his patients. He noted in all but one a marked increase in weight. No special forced feeding was followed. In some the iodide was given at the same time, but the addition of the sarsaparilla to the other measures caused an apparent rate of increase in weight. The author admits that his report will be received with greatest skepticism, but personally he is convinced of the great value of sarsaparilla.

The Importance of the Colon.—M. S. Monier-Williams refers at length to a patient who suffered from abdominal pain and diarrhea with hemorrhages. A right-sided colotomy was done after all other means of relief had failed. A unique appliance for draining the bowel contents was devised and worn by the patient, who became able to follow his usual calling, but later began to run down again. The rest secured for the colon had practically cured his hemorrhages, but now, the writer believed, he was in danger of losing his life from want of use of his colon. Saline injections were therefore made through the operative fistula, and he immediately improved, but all of a sudden developed purpura hemorrhagica. The injections were discontinued and bleeding again ceased; so the salines were renewed, but again the purpura came on. Hypodermoclysis was begun and well borne. The patient was instructed to completely block the cecal anus at night by a proper plug, which was removed each morning. In this way the contents of the small intestine flowed normally into the large intestine during the night time, but passed through the artificial anus into the bottle during the daytime. The colon had twelve hours of absorption and twelve hours of rest, its working hours being of sufficient duration to keep the patient in good general health, and its resting hours sufficient to keep in check the colitis, which, though still not absolutely well, caused no inconvenience. This method enabled the patient to gain greatly, and his health finally become practically normal. The author can give no reason why the saline injections caused hemorrhage. He concludes that certain modern surgical procedures which deprive the colon of its absorptive functions are not devoid of great evils and even dangers. Finally, he declares that many persons who take each night an aperient of such a character as to produce on the following day a liquid evacuation interfere seriously with their own nutrition, and they should be persuaded to withhold the dose, at any rate, every other night, and so give their large intestines a chance of useful absorption.

Berliner klinische Wochenschrift, April 2, 1906.

The Treatment of Nephritis.—Strasser and Blumenkranz describe observations made in the treatment of nephritics by means of warm baths of considerable duration. The underlying idea was that by keeping the body under conditions which would as completely as possible exclude external vasomotor stimuli, a more equable circulation through the kidneys would be secured. Experimental observations have shown that under ordinary conditions the alterations in volume of the kidney are very considerable, and it was supposed that renal excretion would be favorably influenced by a temporary elimination of these circulatory fluctuations. Observations were made on patients who for an hour and a half were placed in a bath having about the body temperature, and analyses of the urine were made before, during, and after the period of immersion. It was found that the effect of the measure was decidedly beneficial, the excretion of nitrogenous bodies and sodium chloride being greatly augmented, while the total volume of the urine also was considerably increased. The effect on the albumin excreted was less noticeable. The authors consider that the method has practical possibilities and suggest that one or two baths daily of from one to one and one-half hours' duration be tried in suitable cases. More prolonged immersion than this was found to yield less satisfactory results.

The Portal of Infection in Tuberculosis.—Uffenheimer attacks the standpoint of Baumgarten, who maintains that in all cases of tuberculous infection distinct lesions are produced at the portal of entry of the germs. The author believes that his experimental observations justify the opinion that tubercle bacilli can pass through the intestinal wall without giving rise to local lesions, and may then form the starting point of glandular disease. He describes a number of experiments in animals in which tubercle bacilli were given by the alimentary tract under conditions which excluded possible errors through aspiration infection, and in which at autopsy marked glandular involvement was found with no demonstrable lesions in the intestinal wall. In some cases tuberculosis of the lymphoid patches was detected, but this the author believes was due to a retrograde infection from the mesenteric glands, and to prove this he cites a case in which diseased mesenteric glands were found in an animal that had been inoculated subcutaneously, and in which the autopsy also revealed extensive disease of all the glands.

Münchener medizinische Wochenschrift, March 20 and April 3, 1906.

The Action of Light on Ferments.—Jodlbauer and Tappeiner supplement their former observations on this subject by some further studies. They have already demonstrated that direct inhibition of the action of the ferment invertin through sunlight from which the ultraviolet rays have been filtered by passage through glass, takes place only in the presence of oxygen. In repeating these experiments with whole light, that is the visible rays plus the ultraviolet rays, by using vessels made of quartz, the authors found that the ferment was affected in the vessels containing hydrogen, nitrogen, or carbonic acid gas from which all oxygen had been removed. This influence on the ferment remained unaltered even when in the course of the experiment oxygen absorbers, such as sodium sulphite or phosphorus, were present in the vessels, whereas control tests in the dark showed that these substances themselves did not damage the invertin. The addition of fluorescent substances such as eosin or dichloranthracendisulphate of sodium did not intensify the action of the light in the absence of oxygen, an observation which is in strong contrast to the conditions which exist when oxygen is present, in which case the intensity of the light action is much augmented.

The Treatment of Acute Inflammatory Processes by Hyperemia.—Lexer, in the course of a very detailed consideration of this subject, arrives at the conclusion that Bier's method has only a restricted field of usefulness and that its application demands a great deal of care to avoid doing more harm than good. He also considers that in all except the mildest cases it is necessary to make use of free incisions through the infiltrated areas. The modifications in the resorptive processes produced by the artificial hyperemia are not a disadvantage in mild cases, but in more serious conditions incisions are necessary in order to protect the diseased tissues from the dangers of diminished absorption and to avoid imperiling the body as a whole through the increased absorption following the removal of the bandage. The increase in protective bodies produced is of little importance as regards the antitoxic substances, is advantageous as far as the bactericidal bodies are concerned in mild cases, but is dangerous in the severe ones through the liberation of large amounts of endotoxins in consequence of the bacteriolysis which results. This disadvantage can be nullified only through extensive and early incisions. The increase in proteolytic ferments which accompanies the treatment is favorable in infected wounds, but the liquifaction of inflammatory exudations must be forestalled by early incisions, as otherwise important tissues may become necrotic or pus may burrow in the neighborhood. The increased transudation or exudation which takes place during the congestion is injurious in closed or insufficiently incised foci, owing to the distribution of poisons in the tissues, but is of value after incision or in infected wounds, through the mechanical washing out of infectious material that follows. The general conclusion is that the treatment by hyperemia is suitable only for light cases, but that if the infection is at all severe early and extensive incisions must be made to render the treatment safe and effective.

Spinal Anesthesia Combined with Scopolamine-Morphine Narcosis.—Penkert reports on 140 gynecological and obstetrical cases, ninety-four of which were major

operations, in which inhalation anesthesia was avoided by combining spinal anesthesia with the hypodermic injection of morphine and scopolamine. One of the great objections to spinal anesthesia for all severe or protracted procedures has been the fact that the consciousness of the patient is not abrogated and that the mental suffering is therefore often very considerable. The author found that by giving 0.02 of morphine and 0.0006 of scopolamine in two injections an hour apart, the first one two and one-half or three hours before the operation, the patients were reduced to such a state of apathy and somnolence that no recollection of subsequent proceedings was retained. The lumbar puncture and injection of the anesthetic solution were carried out as usual, the patient's face was covered, dark spectacles were put on, and the ears were plugged with cotton. On awakening, it was found that not unpleasant memories were retained, that nausea was practically always absent, and that the bodily condition was stronger, so that fluids could be taken very early. The only disadvantage noted was the occurrence of headache in three cases.

The Leucocyte Test in Milk.—Trommsdorff describes observations which corroborate Bergey's statement that the presence of a considerable number of leucocytes in a sample of milk indicates a more or less pronounced infection with streptococci. Trommsdorff suggests a method for estimating the volume of the leucocytes in a definite amount of milk by the use of specially graduated capillary centrifugal tubes. He concludes that the leucocyte test is a useful one which may be employed as a routine measure to eliminate danger from cows suffering from mastitis, and states that milk containing more than one volume per thousand of leucocytes is to be regarded with suspicion, and that if the quantity of leucocytes rises to more than two volumes per thousand, a disease of the udder may be diagnosed with certainty. For routine use heavy glass centrifuge tubes provided with graduations at these two points may be used. In examining the cows in four dairy stables the author found that from 4 to 20 per cent. of the animals were suffering from mastitis, discoverable in this way, but not by the ordinary clinical tests of the veterinarian, and in view of the probable importance of streptococcic milk in the etiology of intestinal disorders of children he urges that more attention be paid to this feature. The infection of cows probably takes place through the hands of the milkers, and as a prophylactic measure the author counsels rigid cleanliness in the care of the animals, and segregation of those whose milk contains streptococci.

Observations on the Spirochæta Pallida and Cytorrhyctes.—Schütz says that he was able to discover both of these organisms together in smear preparations made from young papules that had not yet ulcerated. Cover glass smears are made as thin as possible by the contact method and are stained for twenty-four hours in the original Giemsa solution. The author considers that it is premature to attempt to differentiate the *Spirochæta pallida* from the *S. refringens* on a morphological basis alone, as transition forms indistinguishable from representatives of either class are to be found in great abundance. He describes a considerable number of different appearances assumed by these organisms, and attaches importance to the fact that the neighborhood of red blood cells appears to be a region of predilection for both spirochetes and cytorrhyctes. Schütz also describes a series of observations which lead him to believe that both the spirochetes and cytorrhyctes occur as intracellular parasites in the interior of the erythrocytes, and he finally concludes that these two forms may represent different developmental stages of the same organism.

Deutsche medizinische Wochenschrift, March 22 and April 5, 1906.

The Practice and Theory of Pressure Narcosis.—Brauer says that the method of narcosis under increased pressure for use in intrathoracic operations, which was described by him some time ago, has been found in practice to be both safe and serviceable. In conjunction with Tuffier several operations were satisfactorily carried out by this method. In the one instance a carcinoma of the esophagus was resected, in another case a similar growth was exposed but was found inoperable, and on a third occasion the thorax was opened for bronchiectasis. In the course of these operations, which took considerable time, no disturbances in circulation or respiration were observed, and the anesthetization did not present any difficulties. Tests made on medical patients without opening the thorax showed that the factor of increased pressure did not exert any undesirable effect on heart or vessels, while respiration was somewhat slowed and deepened. The author then enters into a theoretical discussion in which he endeavors to show that the negative pressure method advocated by Sauerbruch and Tiegel presents the same disadvantages and is unphysiological to the same extent as the positive pressure procedure, and that the former possesses no advantages over the latter.

The Care of the Severely Injured on the Battlefield.—Colmers, who was a member of the German Red Cross Committee in the Russo-Japanese war, states that while experience has shown in civil practice that the prognosis is good in cases of perforating wounds of the abdomen that come to laparotomy within five hours after the injury, the results of operations of this sort on the battlefield prove that the best chances for the wounded under these conditions are afforded by securing absolute rest. To this end the author advocates that the members of the ambulance service shall make soldiers with abdominal injuries as comfortable as possible on the spot, but shall not attempt to move them. The place where such wounded are lying should be marked by a flag and at the close of the battle all such patients should be brought to a small local station, which, if need be, can be abandoned to the enemy in accordance with the provisions of the Geneva Convention. An important feature lies in the education of the troops, who should be taught that in the case of an abdominal wound they should avoid all motion and refrain from taking either food or drink in order not to excite peristalsis. By this method of procedure not only will the best chances be given to those having abdominal injuries, but also the surgeons and attendants will be freer to give attention to the less seriously wounded. It is more important to dress properly a large number of less grave injuries than to spend a great deal of time in endeavoring to save the life of a single patient whose injuries are so severe as to render recovery hopeless.

Two Cases of Brain Surgery.—Amberger's first case was that of a boy of six years who sustained an apparently insignificant wound of the forehead in consequence of a fall. Seven weeks later he presented undoubted evidence of a cerebral abscess, and on trephining the site of the former injury a considerable quantity of yellow pus containing streptococci was evacuated. The patient made an uncomplicated recovery and appears to have suffered no ill effects. The other case was that of a man of twenty-two years who for some time after a fall which caused a depression of the frontal bone, suffered from headache, vomiting, and psychical depression. On trephining, a condition of porencephaly was discovered, a cavity easily admitting the finger and communicating with the lateral ventricle being present. This patient also made a good recovery.

Observations on the Transmission of Syphilis to Monkeys.—Neisser, in the first portion of his paper, considers the inoculations that have been made from tertiary syphilitic material, and comes to the conclusion that fresh syphilitic lesions that have not been destroyed by necrosis or suppuration produce typical chancres in monkeys even when they occur in the tertiary stage. It does not matter whether these tertiary forms appear comparatively soon after the infection, or only at a very late period. If gummatous degeneration of the tissues or suppuration has taken place, however, inoculations no longer succeed. Consequently every tertiary manifestation must be regarded as contagious, and every patient exhibiting such lesions is to be considered the carrier of living, transmissible virus. The tertiary forms from which successful inoculations can be made are closed subcutaneous processes, whereas a negative result followed the use of ulcerated material. The localization of the tertiary processes is usually on the extremities, breast, back, etc., where the risk of transmission to others is slight. The tertiary forms, on account of their painfulness or complicating ulceration, rarely remain unobserved, so that they do not frequently come in contact with other persons. The greater danger attending the primary and secondary lesions lies in the fact that these exist in exposed regions—the genitals, lips, and mouth—and are often overlooked while at the same time they are apt to contain many parasites. It therefore follows that several repetitions of an energetic mercurial treatment should be carried out even in the tertiary stage of the disease. The second portion of the paper is devoted to a description of three successful inoculations from infants with hereditary syphilis, which appear to show that such individuals are the hosts of large numbers of parasites circulating in the blood and present in nearly all the organs. Positive results were obtained with the heart's blood, kidney, lungs, liver, ovary, and nasal mucus.

Book Reviews.

STUDIES FROM THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH. Reprints. Vol. III. 1905.

THIS is the third volume of studies compiled by the various workers in the Rockefeller Institute and comprises thirty reprints of articles on quite a range of general subjects, although researches relating to some department of immunity and its congeners preponderate. The collection forms a valuable conspectus of the direction in which modern research is advancing and gives a practical demonstration of the fact that the endowment of the institute that bears his name was one of the best investments ever made by the donor of the funds that enabled these studies to be carried out.

MATERIA MEDICA, PHARMACY, AND THERAPEUTICS, Including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, Minute Directions for Prescription Writing and Avoiding Incompatibility, also the Antidotal and Antagonistic Treatment of Poisoning. By SAMUEL O. L. POTTER, A.M., M.D., M.R.C.P. (Lond.), Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; Author of the "Quiz-Compends of Anatomy and Materia Medica," "An Index of Comparative Therapeutics," Several Articles in Foster's "Practical Therapeutics," and "Speech and Its Defects"; late Major and Surgeon of Volunteers, U. S. Army. Tenth Edition, Revised and in Greater Part Rewritten. Philadelphia: P. Blakiston's Son & Co., 1906.

THIS tenth edition of Potter's unexcelled treatise has been very extensively revised to accord with the changes introduced into the eighth revision of the U. S. Pharmacopeia. Many of the recently introduced non-pharmacopeial remedies have received special treatment, some of the articles of the former edition, treating of the unimportant and obsolete drugs have been dropped, and a large number of the other articles have been rewritten and expanded. The work is divided into three main parts, following an introduction dealing with definition, pharmacology, classification of remedies, and dosage. Part I is devoted to materia medica and therapeutics; Part II to pharmacy and prescription writing, and Part III to special therapeutics, the diseases being arranged alphabetically so as to afford a convenient index of treatment. An appendix contains a list of Latin words with their abbreviations and English equivalents, tables of differential diagnosis, and the formulæ of the most popular patent medicines. A very complete index closes the book. The various sections of the work—Classification, Materia Medica, Incompatibilities, Extemporaneous Pharmacy, Special Therapeutics, Appendix, and Index—are indicated by a thumb index, greatly facilitating ready reference. We have expressed our appreciation of Dr. Potter's treatise in reviews of former editions, and what we might say of this would be only a repetition. It is a work meeting all the requirements of the student and practitioner, systematic in arrangement, clear in definition, concise, yet inclusive. All the changes in this new edition are in the line of improvement and serve to keep the book in the front rank of works devoted to this most important branch of medicine.

THE DISEASES OF INFANCY AND CHILDHOOD, for the Use of Students and Practitioners of Medicine. By L. EMMETT HOLT, M.D., Sc.D., LL.D., professor of Diseases of Children in the College of Physicians and Surgeons (Columbia University), New York; Attending Physician to the Babies' and Foundling Hospitals, New York; Consulting Physician to the New York Infant Asylum, Lying-in Hospital, Orthopedic, and Hospital for the Ruptured and Crippled. Third Edition, Revised and Enlarged. New York and London: D. Appleton and Company, 1906.

EVERY text-book in medicine, which is of any value at all and not a mere compilation such as could be written by any literary hack, is characetrized by some special feature which distinguishes it from its fellows. No work is superlatively good, just as no practitioner is superior in every branch of his calling. The peculiar excellence of the book before us is to be found in the section on symptomatology and diagnosis. The author is an acute observer and not only views the picture of disease as a whole with a comprehensive eye, but singles out the details with an acuteness of vision and notes their significance in a way that is most helpful to the duller of comprehension. We know of no treatise on pediatrics nor of one especially devoted to diagnosis in which the clinical picture is portrayed more clearly and more satisfactorily. With this as a guide, the student or young practitioner should seldom be feezed, so far as recognition of the condition present is concerned, by any case of disease in a child with which he may be confronted. The course of the disease and its characteristic symptoms are so lucidly depicted that no one, with a little study and exercise of discrimination, can fail to recognize the condition.

We cannot say so much, however, concerning the sections on treatment. The orthodox methods of handling the various diseases are correctly stated, but conservatism is not always commendable and sometimes is harmful. A text-book should, of course, give the accepted and conventional modes of treatment, but it should also take note of the newer methods, even those advocated by the therapeutic optimists. In the management of cerebrospinal meningitis, for example, Dr. Holt merely mentions warm baths as of possible value in the relief of the nervous symptoms, but says nothing of them as a curative measure, although they are advocated by many authorities as the best means of preserving life. In pneumonia, again, no reference is made to the specific treatment of the disease, and, though fresh air is referred to in general terms, no mention is made of the open-air treatment. We would not be understood as condemning this treatise, which is one of the best works on the diseases of children which this country or England has produced; we have only pointed out what we think is its weak point. It has strong points enough to make it indispensable to the general practitioner and the pediatrist, but, like most books of the kind, it is not all-sufficient in itself and needs to be supplemented by others of its class. An excellent feature of the work is the illustrations. These are, for the most part, original, are well chosen, and give very clear pictures of the anatomy and chemical aspects of disease in children. This new edition has been revised especially in the chapters dealing with the examination of the sick child, hypertrophic stenosis of the pylorus, diarrhea and dysentery, vaginitis, cerebrospinal meningitis, mental defects, chondrodystrophy, status lymphaticus, and diphtheria.

MAN AND HIS POISONS. A Practical Exposition of the Causes, Symptoms, and Treatment of Self-Poisoning. By ALBERT ABRAMS, A.M., M.D. (Heidelberg), F.R.M.S., Consulting Physician Denver National Hospital for Consumptives, the Mount Zion and the French Hospitals, San Francisco; President of the Emanuel Sisterhood Polyclinic; Formerly Professor of Pathology and Director of the Medical Clinic, Cooper Medical College, San Francisco. New York: E. B. Treat and Company, 1906.

THE author of this book is a specialist in the unconventional, an expositor of the unconsidered in medicine, and an original thinker who has brought to light many indices to disease hitherto unrecognized by clinicians. Autointoxication is an admitted cause of many human ills, but its importance as an etiological factor of disease, especially of nervous and mental diseases, has been somewhat neglected by students of bacteriology. To atone for this neglect by directing the attention of medical practitioners to the influence of man's self-generated poisons in the causation of some of his sufferings, is the *raison d'être* of this work. The book is disappointing in a way and is not very easy reading, owing to a certain lack of system in its composition. The author dives into a multitude of subjects having no apparent relation to autointoxication, and his style is rather jerky, the sentences being short and aphoristic. There is much meat in the book, however, and it is good for desultory reading, though too much like a scrap-book to serve as a logical treatise.

A MANUAL OF PHARMACY FOR MEDICAL STUDENTS. By M. F. DELORME, M.D., Ph.G., Instructor in Materia Medica and Pharmacy, Long Island College Hospital; Member Kings County Medical Society, Associated Physicians of Long Island; Physician to Lutheran Hospital, etc. New York: The John C. Lindsay Company, 1905.

THE author offers this volume as "a textbook of pharmacy adapted to the requirements of the medical student." Parts of the book may be useful, but the chapter dealing with prescription writing has many errors (typographical and others); and until these are corrected the medical student will do well to be on his guard in reading the work.

REFRACTION, Including Muscle Imbalance and the Adjustment of Glasses. By ROYAL S. COPELAND, A.M., M.D., Professor in the University of Michigan, and ADOLPH E. IBERSHOFF, M.D., Instructor in the University of Michigan. Philadelphia: Boericke & Tafel, 1906.

THE subject treated of in this volume is one of much importance and cannot be written up too often, provided the text is of sufficient excellence. This new claimant for favor from the ophthalmologist is a volume of 144 pages. Its style is elementary, the book being designed for the student and general practitioner rather than for the specialist. The portion of the work treating of refraction occupies the first 117 pages. This is followed by an appendix devoted to the description of mechanical aids to refraction. The principles laid down and the advice given are correct, and the book is suitable for those for whom it is intended.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 2, 1906.

DR. SAMUEL LLOYD IN THE CHAIR.

Thyroidectomy for Exophthalmic Goiter (Two Cases).—Dr. W. A. DOWNES presented these cases. The first was a married woman with a negative family history. Two years following a shock of severe character she had nervous spasms which lasted three or four weeks, and, during the year following, she had several similar attacks. One year ago she began to notice tremors, which were at first periodical, but soon became constant. At the same time there was an enlargement of the thyroid and exophthalmos. The tremor was so severe that she was unable to work, to write or sew, or follow any employment; she was practically an invalid. This condition was accompanied by a marked erythema and profuse sweating, headaches, and diarrhea, relief being obtained only by rest in bed. On admission to hospital the thyroid was noted to be of fairly good size on the right side, being but little enlarged on the left side. The exophthalmos was very marked. The application of the ice-bag kept the heart's action down to 100. At operation he removed the entire left lobe and the isthmus. Photographs were shown of the patient before and after operation, showing the marked improvement which followed thyroidectomy. The tremor entirely disappeared at the end of one week, and her pulse went down to 80 by the tenth day. All the symptoms disappeared in time, and she was now attending to her housework without inconvenience. She gained fifteen pounds in weight and claimed that she felt better than she had for years. He believed these cases could be cured, and yet the exophthalmos still remain; why he did not know. Scopolamine-morphine anesthesia was employed. The second patient was a woman, 27 years old, who had typical Graves' disease of long standing. The symptom that bothered her the most was the irregular heart action. She was unable to work. At operation the entire gland was removed except one-quarter of the left lobe. The gland was about the size of the two closed fists, the exophthalmos being tremendous. The heart's action was only about 100. Four or five weeks after the operation quite a marked attack of myxedema appeared, which disappeared eventually without treatment. Since operation she steadily improved and now considered herself well.

Dr. JOHN ROGERS congratulated the doctor upon his good results, and said the employment of the local anesthetic he used had given rise to much discussion. But anyone who had watched the performance of these operations with local and with general anesthesia could not but be impressed with the advantage of the local form, in that there was less mauling and pulling of the gland and, therefore, less squeezing out of its toxic secretion.

Dr. FRANZ TOREK said he had had a case of exophthalmic goiter operated upon and supposed to be cured three years after operation, but during the fourth year there was a recurrence and the condition was as bad as before the operation. The operation consisted in the removal of one lobe. When the recurrence occurred thyroidine was given, but without good effect, and, therefore, a second operation was performed, taking away a good portion of the remaining lobe, cure following. He did not know whether this so-called cure would be permanent or not. The second operation was performed one and one-half years ago.

Dr. WILLY MEYER referred to a patient he had operated upon who had a specially stormy convalescence, and later he found her with the exophthalmos remaining. That was one symptom which seemed to persist in many cases.

Dr. JOHN ROGERS said he was impressed with the improvement in the exophthalmos; the thing was not an organic affair, no organic tissue being left; it was a purely vasomotor change. He emphasized the importance of care in using the cytotoxic serum and spoke of one case in which he had used it; four hours after he was sent for hurriedly, the messenger stating that the patient's eyes were coming out of her head. The exophthalmos was so pronounced that the lids closed over the posterior surface of the eyeball. After two hours this disappeared.

Dr. Downes closed the discussion.

Patient Cured by Implantation of Silver Wire for Large Abdominal Aperture; Well Five Years After Operation.—Dr. WILLY MEYER presented a woman who had a vaginal hysterectomy performed by another surgeon in 1894; during her convalescence it became necessary to remove her left ovary and left kidney. Following this there was much trouble in the healing of the wound, and she developed a median ventral hernia and was again operated upon, but the hernia returned when she lifted a heavy weight. Operation was refused by many surgeons she then consulted, none believing it could be cured. Dr. Meyer saw her in 1900. At the operation he stitched the omentum to the border of the almost round hole, in which he was able to place his fist, then peritoneum and skin were closed by continuous suture. Cure followed; later recurrence. In 1901 he reopened the wound, stitched the omentum again around the border of the aperture, from which it had torn loose in part, and then introduced a silver filigree plate 6 x 8 inches. It was sutured in place with continuous silver wire sutures. The wound healed by first intention, and patient was again cured. She weighed 250 pounds and was a cook. One day she struck her abdomen, which was very pendulous, against the sink and had a partial recurrence of the rupture. In the spring of 1901 Dr. Meyer again reopened the abdomen and found that the filigree had been perforated in the center, broken in two, and the hernia had reappeared in the center. Silver wire was now introduced, a net with narrow meshes made, and permanent cure followed. Dr. Meyer said that in these cases the implantation of silver filigree or silver wire was the only method promising a cure.

Case Illustrating Result of Implantation of Silver Wire, for Defects of Abdominal Wall, Several Years After Operation.—Dr. MEYER expected to show several such cases, but the cold weather kept all away but one, an unmarried woman, upon whom he had operated for a large ventral hernia over two years ago. There was a very large opening and he applied a ready-made silver filigree, with perfect results. Altogether he had had fifteen operations upon fourteen patients; twelve had been successful and three had failed.

Result of Plastic Operation for Carcinoma of Cheek.—Dr. FRANZ TOREK presented a man who had had a carcinoma of the cheek, which required, in its removal, the taking away of a large amount of tissue, especially healthy tissue; this left a large defect, which called for some plastic operation. The skin of the neck was utilized for this purpose, a large flap being made and turned over, so that the skin occupied the place formerly occupied by mucous membrane, the raw surface being turned outwards. A second operation was done, cutting the flap at its base and turning it up and over, so that the two raw surfaces came in contact, thus obliterating the raw side. Where the flap had been turned upon itself naturally a sinus was left, which was closed at a third operation. There was now a crop of hair on the inner side of his mouth, which apparently was gradually disappearing; if it did not entirely disappear he intended using the *x*-ray upon it or epilate.

Dr. WILLY MEYER said that he had seen two patients with regular beards in their mouths as the result of such a plastic operation, and they certainly were in a terrible condition. This was before the days of the *x*-ray.

Dr. HOWARD LILIENTHAL referred to a case in which a urethroplasty had been performed and the new urethra was choked by hair growing there, and the whole operation had to be done over again.

Dr. Torek said that he had followed up one case, and four months after operation hair grew as long as three

inches, disturbing the patient greatly in swallowing. The hairs were pulled out and never grew again.

Excision of Rectum, Sigmoid, and Transverse Colon, with Closure of Two Artificial Ani.—Dr. SAMUEL G. GANT reported this case. The patient was to have been presented, but failed to appear. The various operations performed upon this man were caused by an intractable diarrhea which began in 1888 and which could not be relieved, the result of stricture. The patient was operated upon by Dr. Kelsey of New York, Dr. Berneys of St. Louis, and by Dr. Gant. When Dr. Gant saw him the patient had two artificial ani, one discharging pus, the other discharging feces and an acid fluid which excoriated the skin. Dr. Gant performed a series of operations which relieved the patient.

Report of a Case of Appendicostomy.—Dr. GANT presented this case also. The patient was admitted to the hospital suffering from diarrhea. High colonic irrigations were used, which seemed to relieve him of his attacks for two or three weeks only, when they would recur. Extensive ulcerations were found; a simple hypertrophic proctitis had gone on to ulceration. Appendicostomy was performed and the patient had gained fifty pounds since operation. Dr. Gant said that he knew of no operation which would give such immediate results as appendicostomy in these cases.

Dr. R. H. M. DAWBARN spoke of a point in the technique first brought out by Dr. Meyer. At the time of operation he said it was wise for one not to take it for granted that there was no stricture in the appendix, but, after turning the appendix out, one should make sure of it by passing a catheter. A recent case of his had a chronic ulcerative colitis, presumably tuberculous. Every injection produced a crampy pain until an alkali was added. Since this patient had had a previous attack he said it was conceivable that a third attack would follow, and he, therefore, believed it would be a wise thing to leave the appendicostomy opening, covering it over with a pad. The annoyance caused by a tiny fistula was the lesser evil by far.

Dr. FRANZ TOREK uttered a note of warning in appendicostomy operations when the flushings were made by one not experienced, because of the possibility of rupturing the appendix and the fluid passing into the abdominal cavity In a case of this kind that he reported the patient died from shock, and not from a suppurative peritonitis. Access to the cecum should be the most direct possible.

Dr. Gant believed in leaving the appendix projecting about one-half an inch above the skin, so as to aid the nurse in finding the opening into it.

A Case of Marked Mental and Physical Improvement Following Nephropexy in an Insane Patient.—Dr. WARREN S. BICKHAM reported the case of a woman, 37 years old, who was admitted to the Manhattan State Hospital suffering from hysterical insanity. On admission she was depressed, hypochondriacal, quiet, compliant, connected in conversation, and reacted normally to her surroundings. She spontaneously spoke of nervous and hysterical attacks beginning seven years ago, and which had increased in intensity; of stomach troubles; of fainting attacks; of choking sensations; of fear of death, and of doing herself bodily harm. Her physical symptom-complex showed a poorly nourished woman, gait weak and staggering, poor muscular power, impaired sight of right eye, exaggerated reflexes, tremor of tongue, hands, and facial muscles, gastrointestinal disturbances, dull pharyngeal reflexes, subjective complaint of cardiac, pulmonary, and gastric distress, suffocating sensations, and a pulse variable in frequency. Her mental symptom-complex showed her emotional attitude was one of depression with many hypochondriacal complaints, marked instability in her emotional control, subjective complaints of shortness of breath, cardiac palpitation, fear of death, and various phobias. Dr. Robert C. Kemp found that she had a chronic gastritis and hyperchlorhydria, a displaced right kidney, a gastroptosis, etc. A right nephropexy was performed. The patient then showed an improved nutrition and her hypochondriacal complaints became less, and as her improvement in mental and physical condition improved she became hopeful of the future and manifested a desire to be at home. She gained thirty-five pounds in two months. During convalescence she was given electric and vibratory treatment. Her insanity was considered to be cured.

Dr. ROBERT T. MORRIS reported two cases of melancholia, both apparently well three years after operation of nephropexy. He did not believe that the major psychoses were caused by loose kidneys, but that the symptoms were precipitated by them and he, therefore looked upon floating kidney so called as a precipitating factor. One should not operate upon such cases for the purpose of curing the phychosis but to cure a definite tangible defect.

Cases of Wheel Injuries.—Dr. ROBERT T. MORRIS presented two cases, a man and a boy, who had been run over by heavy vehicles. The boy had sustained a compound comminuted fracture of the arm, without injury to the main nerves; while the man received no fracture of the arm but had musculospiral paralysis with its wrist drop, etc. The boy's arm was sealed, Dr. Morris depending upon the germicidal power of the blood; the bones were crushed or smashed. Both patients made good recoveries.

Wheel Injuries, Especially Those Due to Automobiles and Other Rubber-tired Vehicles.—Dr. E. M. FOOTE said that there was no word in English to express the injury due to the passage of a wheel of a vehicle over the human body. He suggested the term "wheel injury" as analagous to "gunshot injury," a phrase in common use. No satisfactory explanation had ever been given of the marvelous escapes from serious injury when persons were run over by heavy vehicles. The writer explained such escapes by saying that every part of the body had some very resisting structures, as well as some tender ones; that the wheel in its passage over the body was lifted a certain distance from the pavement by the resisting structures, bones, contracting muscles, etc., forming thus an irregular curve from the time that its rim left the pavement until it touched it again on the other side of the body. This curve was spoken of as the "dead-line." Whatever structures determined the summit of this curve, must bear the full weight of the vehicle plus whatever additional impact the speed of the vehicle imparted. If they escaped injury, it was because of their own strength. Organs which lay to the side of this summit, and beneath the "dead line," or were sufficiently elastic to be pushed beneath it without injury, were perfectly protected This explained why the intestines often escaped injury, when a wheel passed directly over the center of the abdomen. If the force was not great enough to crush the spinal column, everything else was safe unless it happened to be caught between the wheel and the spine. The mesentery had less chance of escape and was very frequently injured in accidents of this character. The writer hoped by experiments to learn just what structures were the most resisting in every part of the body, and how many pounds of pressure they could withstand with safety. When these facts were known, the surgeon who saw a patient after such an accident would be in a much better position to judge whether an operation was necessary or not. Clinical data were also essential and would add very much to our knowledge of this subject if those who were called to see patients suffering from wheel injuries would make note of the following facts: Sex, age, date of injury, type of automobile, weight when empty, number of occupants or character of load, speed (fast, moderate, slow), character of road surface; was patient struck by machine before being run over? How was patient lying when struck by wheel? Immediate symptoms, external injuries, internal injuries (early symptoms, late symptoms), result. The speaker requested that anyone called to see a patient suffering from wheel injury, would report to him, giving facts here noted, to enable him to pursue the study of this fruitful topic.

Dr. HOWARD LILIENTHAL said that Dr. Foote had opened up a new field for observation and thought the subject might be worked up so that if one knew the kind of vehicle and the kind of a road much information might be

given regarding what kind of an injury to expect. The so-called "dead-line" would have to be varied according to the speed of the vehicle.

Dr. R. H. M. Dawbarn said that it was a well established fact that with greater speed, greater difficulty was encountered in keeping the vehicle on the ground and little obstacles, like a cane, or even a pebble, would sometimes cause the automobile to go into the air and over considerable space.

Dr. Foote closed the discussion.

The Use of Silver Wire for the Cure of Large Hernias.—Dr. Joseph Wiener, Jr., drew attention to a somewhat neglected field of reparative surgery. The more he used silver wire for the cure of hernias the more convinced had he become to its value. The subject was first brought to attention by Witzel and Goepel, almost simultaneously in 1900. With the exception of articles by Willy Meyer, Bartlet and Perry, little had been written on this subject. The filigree he employed had been that devised by Bartlet, and he followed his directions closely. He advised the use of the ready made filigree made of thin wire, not heavier than gauge number thirty. An advantage of filigree over silver wire sutures was the fact that it could be introduced very quickly and could be placed between tissues at a much greater distance from the edges of the opening than would be possible in passing a needle. It should overlap the hernial opening on all sides. No sutures were required to hold the filigree in place, and so it could better adapt itself to the surrounding tissues, and there was less likelihood of its causing any irritation. If properly made and properly introduced it could cause no discomfort whatever; the patient would not even be aware of its presence. The form of filigree used by Dr. Wiener was that devised by Bartlet and described by him in his article in Volume 38, *Annals of Surgery*, 1903. In ten cases in which Bartlet used it, he had never had to remove it, and some of his cases had been under observation two years or more. Dr. Wiener said that five of the cases he reported were in Dr. Lilienthal's service. In a private case the wire was used for a ventral hernia following a median celiotomy. In two cases there were large inguinal hernias with wide separation of tissues. One case was an umbilical hernia, one a ventral hernia following an injury, one a ventral hernia following an operation, and in no case was it necessary to remove any of the wire.

Silver-wire Cable Suture-Material.—Dr. Howard Lilienthal presented this apparatus which was made of very fine wires, possessed great pliability, could be tied into a knot and, therefore, need not be twisted, was very strong, and possessed the decided advantage in that the scar tissue grew into its interstices and closed over better. The wires were so fine that they did not produce irritation of the tissues. After being tied in a double knot, it could be cut close and would not untie.

Dr. Willy Meyer said that he had operated on quite a number of his fifteen cases with implantation of silver wire netting, made during the operation, but he used the one made of ordinary silver wire; he emphasized the point that the ordinary silver wire would answer the purpose.

Dr. Joseph Wiener, Jr., said that the cable wire was exceedingly pliable and superior to the ordinary silver wire. Instead of using one filigree one might use several in hernia operations, as advocated by Bartlet. It was far preferable to use a filigree of silver wire for closing these large apertures than to depend upon an attenuated muscle for this purpose.

Stated Meeting, Held March 2, 1906.

Dr. Samuel Lloyd in the Chair.

Obstruction of the Ileocolic Valve and Appendicitis, from Ulceration of the Caput Coli and Adjacent Portion of the Ileum; Resection.—Dr. Walter M. Brickner presented this report and specimen. The patient was a man, aged forty-six, who for many years spent much of the day in the composing room of an evening paper, handling a good deal of warm type, much exposed to the fumes of lead and antimony. He had not had any of the ordinary evidences of lead poisoning. The present ailment began five years ago, and for about four years he had had irregular attacks of abdominal pain, lasting but a minute or two. They usually came on just as the patient sat down to eat, and they seemed to be associated with constipation. Recently he noticed that intestinal gurgling preceded the pain. In March, 1905, the attacks changed in character, severe attacks of pain occurring across the abdomen, lasting all night. There was no fever. Thereafter the attacks recurred at intervals of two or three weeks, usually at night. The patient could predict their appearance when he had no movement of the bowels, or when he indulged in hearty eating. The only positive findings on physical examination were marked tenderness and resistance in the right iliac region. Rectal examination was negative. Dr. Brickner gave the tentative diagnosis of chronic appendicitis, with a strong suspicion of some obstructing factor, possibly intestinal adhesions. After being admitted to Mt. Sinai Hospital the patient was placed in the hot bath to secure complete relaxation, and there was felt in a tender area an object which in size, shape, and location corresponded with the appendix. At operation the suspected rectrocecal appendix was found; it was obliterated at the tip and contained a drop of pus at its thickened base. The caput coli was much thickened. While the appendix was being tied off a small rent appeared in the cecum, which rapidly spread through the brittle tissue and soon gaped widely across the fundus of the cecum. The index finger passed into the gut showed the caput coli to be the seat of extensive and numerous ulcerations. No less radical an operation than resection could be contemplated, and about three inches of the ileum and four inches of the colon were resected and an end-to-end anastomosis performed easily. The following morning the pulse rose to 116 and continued to rise steadily to 130 by evening, when coffee-ground vomiting began. Reopening the wound, the speaker found no gross evidences of peritonitis and the site of anastomosis was satisfactory. The patient died on the following day, forty-eight hours after operation. The entire caput coli was found to be thickened, and its mucosa the seat of several rounded ulcerations, closely grouped. The ileocecal valve was the seat of inflammatory infiltration, almost occluding it. There was much edema. The condensed pathological report was that the mucosa was hemorrhagic and infiltrated with inflammatory cells. At the points of ulceration the mucosa was entirely necrotic, the muscular coat covered with a layer of fibrin. The remaining layers of the intestine showed inflammatory infiltration. The ileocecal valve was markedly infiltrated and was edematous. The ileum near the valve was also ulcerated. There were no microscopical evidences of tuberculosis, syphilis, or new growth. The cause of the ulcerations was undetermined. For lack of a better term, the condition must be called stercoraceous ulceration of the cecum. In closing, he said that of the few cases of ileocecal obstruction due to inflammation, no two, however, had presented the same appearances.

Dr. John F. Erdman asked how Dr. Brickner was able to make an end-to-end anastomosis unless the ileum was markedly dilated. Unless the ileum was considerably dilated there was great danger of leakage.

Dr. Emanuel Libman, referring to the difficulty of diagnosis, said that the tenderness in the deep iliac fossa had nothing to do with what was found at operation. The appendicitis in this case was in all probability set up by disease of the cecum. The symptoms produced were due to recurrences of the attacks of swelling of the cecum and ileocecal valve. It was impossible to say what the type of ulceration was.

Dr. Albert A. Berg said the most interesting point was whether the appendicitis was the primary cause, or was it

secondary. He had operated upon a number of cases in which the chronic form of appendicitis was accompanied with some thickening of the caput coli, as well as the parts above the ascending colon. With the paralyzed condition of this portion of the bowel there would be found conditions necessary for fecal stagnation in the caput coli which would tend to induce ulcerative conditions of the mucosa of the intestine.

Dr. Alexis V. Moschcowitz reported briefly a case in which the diagnosis was appendicitis. This diagnosis was concurred with, but the opinion was expressed with mental reservation that there might be a tumor of the cecum. The patient was sent to the hospital for resection of the cecum or ileocecal junction. The cecum was found to be thickened, with a distinct stenosis of the ileocecal valve. Several inches of the ileum were resected, as well as the adjacent portion of the cecum, and a side-to-side implantation of the ileum into the colon made. At the end of a week there occurred symptoms of acute intestinal obstruction, and the constriction was found to be caused by an organized band of tissue. The patient died on the day following the operation, and the specimen showed a papillary colitis with a stricture that would admit an ordinary lead pencil.

Dr. Samuel Lloyd said that two weeks ago he was called to see a patient in Princeton who had an appendicitis with a secondary infection of the colon; he found a large number of ulcerations.

Dr. Brickner, closing the discussion, said that the disparity in the size of the colon and ileum was not so great as to cause any difficulty in doing an end-to-end anastomosis; that the anastomosis was satisfactory was shown twenty-four hours after operation. The appendix in this case was not at all adherent.

Stricture of the Esophagus, Showing Good Results Three Years After Operation.—Dr. Charles R. L. Putnam presented a child, five years old, who gave a history of having swallowed a solution of caustic potash two and a half years ago, burning the throat, etc., with a gradual increase in difficulty in swallowing. When Dr. Putnam first saw the patient, she had emaciated to the last degree and was so weak she could not sit up without being supported. A stricture was found eleven inches from the incisor teeth. As improvement did not follow admission to the hospital he dilated the stricture according to the method of Dunham. As it was impossible to make the child suck the thread through a drinking tube, he was forced to pass it through a catheter in the nose. The water was then allowed to flow drop by drop into the pharynx, and the patient was encouraged to swallow frequently. When once the thread was started it passed readily into the stomach. The day following he did a gastrostomy after the method of Robson and Frank, and, four days later, hooked the thread out of the stomach. Three days later a whipcord was tied to the silk at its abdominal end and drawn out through the mouth, requiring a good deal of force. The epiglottis was protected by a bent metal tube, through which the cord was threaded as it came out of the pharynx. By a like tube the cardiac orifice of the stomach and the abdominal fistula were protected. The tube, by following the cord, easily found the opening of the esophagus. Later piano wire with a metal olive attached to its center was drawn through the stomach alongside the cord by the silk thread, which had also been left in place. The upper end of the wire was drawn out of the mouth until the bulb became impacted in the stricture. It was then held firmly while the cord was gently moved up and down like a saw. So soon as the bulb slipped through it was drawn up through the mouth and a larger one used at the same sitting, or a few days later. The esophagus was dilated in two sittings up to 23 Fr., after which bougies on guides were used through the mouth, twice a week for several months. The patient was then lost sight of for some time. She returned later, saying a piece of meat was in her throat; after passing a guide into the stomach she was able to swallow perfectly well. Bougies were again passed once a week, the size used being about 26 Fr. There had never been any leakage from the stomach opening, and it closed within a few weeks after manipulation through it was discontinued.

Resection of the Stomach, Performed Fourteen Months Ago, for Carcinoma.—Dr. Franz A. J. Torek presented this patient. He said that the statement often made, that a carcinoma of the stomach was no longer operable when it could be distinctly felt, was not discriminating. In this case the tumor was large and could not only be felt but seen. The operability of carcinoma of the stomach depended upon the question whether one could operate well beyond the limits of the growth, whether it was possible to remove affected glands, and whether or not neighboring organs were involved. In the case presented, Billroth's first method was followed, the stomach being joined to the duodenum by a Murphy button. The patient was in excellent health and had gained forty-five pounds.

Dr. Albert A. Berg spoke of the question recently brought up by Boas in reference to inoperable carcinomas of the stomach when palpable, following a careful study of malignant disease of the gastrointestinal tract. By a careful analysis he was able to state that of thirty cases operated upon within a period of twenty days after the first manifestations of the symptoms, it was found that in only four of these cases was a radical operation possible. In the vast majority of these cases no operation at all could be done. On the other hand, Boas found that cases going on for one year, the tumor being distinctly palpable, if submitted to operation, a radical procedure was possible. His conclusions were that there were a number of cases of carcinoma of the stomach inoperable from the beginning, *i.e.* they never gave symptoms when in an operable stage; when symptoms appeared they were no longer operable. Slowly-growing forms of tumor were not so malignant and were the best cases for radical operation. Boas was able to say that it was the slow-growing forms of carcinoma that formed favorable instances for surgical interference.

Dr. Torek said that more discrimination should be made in these cases. Regarding the time element in such cases, he knew that fourteen months was not sufficient to base results. The best statistics came from Mikulicz, who considered patients cured if they were well one year after operation.

Case Illustrating the Combined Operation for Appendicitis and Inguinal Hernia.—Dr. Torek presented this patient. The incision began at a point between the superior spine of the ileum and navel, one-quarter of the length of this line distant from the iliac spine, and ended over the external inguinal ring. The aponeurosis of the external oblique was split as in appendectomy, but the incision was carried down into the inguinal ring. The aponeurosis was dissected off and Poupart's ligament was exposed. The hernia operation was completed up to the point where the sac was divided. Then the appendicitis operation was performed in the usual manner by splitting the fibers of the muscles. This operation was completed to the point of closing the muscles. The aponeurosis of the external oblique was still left open. Now the deep layer of hernia sutures was applied, uniting the internal oblique and transversalis muscles to Poupart's ligament, and then the aponeurosis of the external oblique was sutured, covering the site of both operations. Lastly, the skin was sutured. The operation took but little longer than the hernia operation alone would, and the fact that the aponeurosis was divided but once secured greater strength than if two separate operations were made.

Two Cases of Volvulus of the Small Intestine with Unusual Features.—Dr. Albert A. Berg presented these patients. The first was a girl who was admitted to Mt. Sinai Hospital last summer, with the history that she had never been ill before. She never had any trouble in her abdomen until nine months prior to admission, when she began to vomit, and cathartics administered failed to cause a bowel movement. The vomiting was not a malignant

one. High and low enemata were given during nine days, with absolutely no movement of the bowels. When she entered the hospital she was in fairly good condition, pulse 120, with abdomen distended. Across the abdomen was noted a distended loop of intestine about the caliber of the forearm, while below it was a groove one inch in width; the circular distention was composed of coils of intestine whose caliber was somewhat less than the child's forearm. The caput coli was collapsed, as also were the transverse colon and sigmoid flexure. It was evident that the seat of the obstruction was proximal to the ileocecal valve. Laparotomy was decided upon. The intestine was found with its peritoneal coat completely split from it for several feet; the coat was thickened and split in several directions. The distended intestine was found to be the small one. Running along from its wall were multiple small diverticula between the muscular fibers of the intestine. The wall looked like masses of currants. After evacuating gas and fluid matter the opening was closed. The intestine was delivered and a complete turn found in a direction opposite to the hands of a clock, four inches from the cecal junction. After uncoiling this the intestines were replaced, the abdomen closed, and a perfect recovery followed. This case was of particular interest because of the spontaneous rupture of the peritoneal coat, and also the multiple diverticuli of the small intestine.

The second case presented symptoms of intestinal obstruction, repeated vomiting, inability to obtain a movement of the bowel, etc. There was no temperature, but the pulse was increased in frequency. At operation a volvulus of the small intestine was found, the seat being six inches from the ileocecal junction. There was a coil or turn of one and a half in the direction opposite to the hands of the clock. There was no gangrene. The volvulus was quickly and easily uncoiled and the intestine replaced. An enteric fistula formed, but this closed at the end of the fourth day. This was followed by a slight leakage, but a plastic operation completely closed this and the child made a good recovery.

Case of Echinococcus Cyst of the Liver.—Dr. Albert A. Berg presented this patient, a woman, who had been in this country but nine months. She never had had anything to do with dogs or cattle, and there was nothing in her history which could account for the development of the echinococcus cyst. She had no temperature. She was slightly jaundiced, the sclera being slightly tinged, and there was a small amount of bile in the urine. She was somewhat emaciated. The enlargement of the liver was smooth and no masses could be felt in the abdomen, leading to the impression that there was some malignant process in the liver secondary to intestinal or gastric carcinoma. Aspiration was done and this yielded a clear fluid, in which the hooklets of the echinococcus were found. A subpleural hepatotomy was done, the tenth rib being resected three inches and the pleura raised from the diaphragm without opening it. The diaphragm was incised and the liver packed off, and the large echinococcus cyst removed therefrom. The cyst wall was a single one. The specimen was presented.

Dr. William A. Downes presented the picture of a patient with echinococcus cyst of the liver, the left lobe being involved.

Excision of the Femoral Vein.—Dr. John F. Erdmann presented a man upon whom he had operated and a specimen of the femoral vein which had been excised as far down as Hunter's canal. The patient was thirty-six years old, who had never been ill. During the last two or three years he tapped the shoes of children and had a last in the crotch of the left thigh. He noticed a small lump in the thigh in Scarpa's triangle. He went to a hospital, where an incision was made over the tumor; then the wound was closed, the diagnosis being probably one of aneurysm. When Dr. Erdmann saw the patient the tumor practically filled Scarpa's triangle, pulsations being noted in its extreme outer limit. In six months the patient had lost nine pounds. There was no pain and no swelling of the feet or legs, or other evidences of pressure. The tumor was dissected out from below upward; it extended up under Poupart's ligament into the pelvis. Since operation there had been no edema of legs or feet. No report had been received from the pathologist.

The Contagiousness of Gumma.—Dr. Charles M Williams read this paper (to be published in a later issue).

Dr. L. Duncan Bulkley said that the question raised upon the duration or possibility of infection by any of the lesions of syphilis was an interesting one, and that we must revise our views regarding the real situation. There did not seem to be any reason for saying that if the lesion of syphilis took the form of gumma it should not be as infectious as other lesions of syphilis at that same period, as three years after the initial lesion. The explanation that the location of gumma was not where it was likely to give infection was probably correct. Dr. Bulkley said he could not recall more than four cases of gumma of the penis. None had known of chancre of the finger occurring in those who handled gummatous cases.

Dr. James Pedersen said that we were compelled to change our views regarding syphilis being a clinical entity. He asked if the question did not reduce itself to a consideration of how long syphilis was infectious in a given individual. Did it not turn upon the patient's power of resistance to disease in general, and syphilis in particular, how thoroughly treated, and how he responded to treatment? Were these cases carefully and persistently treated? If syphilis was to be transmitted there must be some open lesion.

Dr. Williams believed that it was very important to determine whether or not syphilis was contagious; any person having a lesion of syphilis, even after many years, he believed to be capable of infecting others. He thought the effect of time in lessening the power of the disease had been overrated. Both time and treatment were important factors in extinguishing syphilis.

Remarks on a New Form of Intestinal Obstruction.—Dr. Alexis V. Moschcowitz read this paper, confining his remarks to one incidental step in the operative treatment of volvulus of the sigmoid flexure, namely, that of prevention of its recurrence. After a very careful search of the literature, he said he had found fifteen cases of recurrence; in addition there were many cases in which there was strong presumptive evidence that repeated attacks of volvulus preceded the one for which operation was done. He felt that he was safe in assuming that these recurrences were not very uncommon. The methods suggested and carried out in order to prevent such recurrences were quite numerous, and he briefly reviewed these various methods. He excluded from the discussion all cases of gangrenous volvulus, and confined his remarks wholly to those cases in which the question arose, What had best be done to prevent a recurrence? He had had occasion to operate upon five cases during the past four years, and sigmoidopexy was performed in these cases with satisfactory results except in one case, which formed the basis of this communication and which he reported in full. S. S., forty-one years of age, was admitted to Mount Sinai Hospital, January 18, 1905. His family history was negative. His past history showed that previous twistings of the gut had occurred. His present attack began like its predecessors, with cramp-like pains in the abdomen, distention, and absolute constipation, neither fecal matter nor gas escaping. Two days previous to admission to the hospital the patient began to hiccough and vomit, the latter becoming fecal. The distention was so great that the anteroposterior diameter exceeded by far the lateral. The epigastric and right hypochondriac regions were occupied by an enormous, semilunar, smooth, rounded, tense, and tympanitic mass, below which coils of distended gut were seen in peristaltic motion. There was no particular point of tenderness, and there was no marked rigidity of the muscles. An enema was given, but the capacity of the rectum was only about six ounces and the injected water returned without either fecal matter

or gas being passed. Incision revealed enormously distended coils of intestine. The general direction of this gut was diagonal, passing from the left iliac fossa upward and to the right, terminating, in the region of the liver by an arch-like formation. It was at least three feet in length and six inches in diameter, deeply injected, and of a deep red, almost purple, color. Danger of rupture seemed imminent. The bowel was twisted around an arc of 360°. After being emptied by means of the rectal tube, the bowel was stitched to the left half of the anterior abdominal wall by a number of interrupted silk sutures. The abdominal incision was rapidly closed by through-and-through silk sutures. The duration of the operation was thirty minutes. In February symptoms of intestinal obstruction again became pronounced and an exploratory operation was decided upon. Upon opening the abdomen, coils of distended small intestine presented. The sigmoid was found adherent to the anterior abdominal wall where it was sutured at the former operation. The coils of distended small intestine were traced to the outer left side of the sutured sigmoid and were apparently incarcerated between it and the lateral abdominal wall. Adhesions were liberated and the intestines replaced into their normal position. The patient died two hours after the completion of the operation. That in theory this operation had caused misgivings in the minds of some authors was shown by a review of the literature on this subject. It made no difference how far to the left we went with the suture, a septum was bound to be created which would divide the abdominal cavity into two halves into which one or more loops of the small intestine might slip and become strangulated. Although he had not been able to find a single case of such an accident in literature, the occurrence of the accident cited proved that sigmoidopexy was not an ideal method. After reviewing Obalinski's, Senn's, Roux's, Reidel's, and Philippowitz's methods of endeavoring to prevent a recurrence of volvulus, he concluded that in all of them there were inherent certain objections. He regretted that he was unable to offer a better substitute than the operations which he had enumerated. In spite of his experience his deductions in regard to the proper procedure had not been materially altered. He was prepared to say that sigmoidopexy was the best possible procedure in order to prevent a recurrence of volvulus. If the general condition of the patient and the local conditions were favorable, he would not hesitate to resect.

Congenital Obliteration of the Esophagus, with Esophagotracheal Fistula.—Dr. Charles R. L. Putnam presented this specimen.

College of Physicians of Philadelphia.

At a stated meeting held March 7, Dr. Wm. L. Rodman exhibited "A Patient in Whom Gastroenterostomy Failed to Relieve Hematemesis and Other Symptoms in Connection with Duodenal Ulceration." As a final resort, it was proposed to perform pylorectomy. Dr. Rodman also demonstrated two cases showing the results of Warren's operation for the removal of benign neoplasms of the breast. The incisions are made below and at the sides of the mammary gland, which as a result can be turned up. The new growth, or perhaps cyst, can then be removed and the gland restored to its normal position. There is no deformity, and the scar is concealed by the overhanging breast. Dr. Charles B. Worden presented a communication entitled "A Clinical Study of Gastroptosis, with Special Reference to Outlining the Stomach." In addition to other measures for determining the size and position of the stomach, such as percussion, inflation, auscultatory percussion, and the use of the tuning fork, *x*-ray pictures were taken after the ingestion of an emulsion of bismuth. Often the results obtained by other means of investigation were merely confirmed, but not rarely information was obtained that otherwise would have escaped attention. A series of interesting conditions was depicted by means of lantern slides, and Dr. Henry K. Pancoast described the technique and exhibited *x*-ray pictures made in the course of the study. Dr. Alfred Gordon read a paper entitled "Is Neuralgia a Functional Disease? A Study Based Upon the Pathological Findings in Eight Cases." In all of the cases degenerative changes in the affected nerves were found, and in four, occurring in persons of mature years, changes in the blood-vessels also were present. Dr. Gordon was inclined to think that the distinction between neuritis and neuralgia is an ill-defined one, and that the changes in neuralgia are essentially peripheral. Drs. Wm. G. Spiller and Chas. H. Frazier read a paper entitled "Upon the Results of Cerebral Decompression." They reported a number of cases presenting symptoms of cerebral tumor, in which the new growth was either not localizable or not removable, but in which an opening in the skull was followed by relief or disappearance of headache, vomiting, optic papillitis, ataxia, paresis, and other symptoms. In some instances the patients were able to do a certain amount of work and to lead useful lives for a number of years. Drs. Spiller and Frazier also presented a communication entitled "Nerve-Stretching for the Treatment of Erythromelalgia." They showed that this disease is dependent essentially upon inflammatory or degenerative changes in the terminations of the nerves involved, and that vascular alterations may or may not be present, and on the basis of this fact they were able in several cases to afford relief from the exquisite pain attending the disorder by stretching of the trunks of the nerves concerned.

Philadelphia County Medical Society.

At a stated meeting held March 28, a symposium on "Sanitary and Moral Prophylaxis" was held. Dr. Prince A. Morrow of New York, president of the American Society of Sanitary and Moral Prophylaxis, delivered an address, in the course of which he gave an outline of the work of the Society during the past year, relating the difficulties by which the medical man is beset in inaugurating a crusade against the conservatism that fosters gross ignorance on the subject of vice and its physical effects. The public needs to be instructed as to the imminent dangers by the medical profession, in conjunction with other influences and agencies. The work of the American Society of Sanitary and Moral Prophylaxis had been instituted along four lines, namely, education of the youth in hygiene and social truths in the home and the school, education of young men and women of the working classes, dissemination of hygienic knowledge in the army and the navy, and education of the general public. Dr. Morrow criticised the newspapers for inserting objectionable advertisements, and for their objection to printing articles of an informing nature in their reading columns. Dr. Edward Martin spoke of "Syphilis and Gonorrhea of the Innocent." He urged the education of children in matters of vital physiology. He alluded to the enormous power of the press and the opportunity afforded of educating the public to a realization of the dangers of vice. Dr. W. M. L. Coplin discussed the question, "What Can Health Boards Do in Limiting the Spread of Venereal Diseases?" He maintained that official supervision of vice does not act as a deterrent. He advocated educational rather than restrictive measures, and he suggested that much could be done through the schools in enlightening young persons in matters of sexual hygiene. Dr. Robert N. Willson, Jr., read a paper entitled "The Influence of the Young Man in the Control of Venereal Diseases." He pointed out the great prevalence of venereal diseases among students in colleges and universities. Dr. Joseph Price presented a communication entitled "The Transmission of Venereal Diseases to the Wife and the Evil Results Thereof." Dr. Wm. B. Hale, managing editor of the *Public Ledger*, spoke of "The Social Evil from the Publicist's Viewpoint." He expressed doubt as to whether the newspaper, going into the hands of old and young,

sophisticated and innocent alike, constituted the best medium for the circulation of warnings against the social evil. The press could, however, contribute largely to the success of the movement by declining to publish matter of a suggestive or inflammatory character. On the press rested the heavy responsibility of keeping the general tone of public sentiment sound and sweet, and thus of furnishing the foundation for the specific work for purity of mothers, the medical profession, and the pulpit. Rev. Dr. Floyd W. Tompkins discussed "The Social Evil from the Viewpoint of the Pulpit." He was opposed to the segregation of vice, and he held that the minister must speak plainly to his people, being sustained in his efforts by the physician.

Chicago Surgical Society.

At a meeting held February 2, 1906, Dr. W. R. Cubbins reported a case of esophageal polyp which he removed by operation. He exhibited the specimen. The patient was a man, forty-five years of age. The tumor was situated on the anterior portion of the esophagus, with the pedicle a little to the left of the median line, just above the larynx and cricoid cartilages, and extending down into the esophagus for about seven inches. It was ligated, the tumor removed, and the wound closed with packing. The tumor measured sixteen centimeters in length, just above the lower end it was rather cone-shaped, and was five centimeters, and at the pedicle one centimeter in diameter. It weighed 210 grams. Dr. B. W. Sippy read a paper on "Diagnosis of Esophageal Lesions." The author took up the functional and anatomical diseases of the esophagus, one of which he said related to sensation, and the other to motility. Sensory and motor disorders were discussed at length. As to ulcer of the esophagus, it seldom occurred except in association with carcinoma. There had been less than forty cases of peptic ulcer of the esophagus reported. By far the most common and serious disorders of the esophagus were related to conditions producing obstruction to the lumen of the tube. He exhibited a specimen of dilatation of the esophagus due to cardiospasm, a gastroenterostomy having been performed for the relief of an alleged pyloric stenosis. Tumors of the esophagus may be benign, but are usually carcinomatous. Sarcoma may invade the esophagus from the surrounding structures. He spoke of diverticula of the esophagus, saying that three forms based on etiology were recognized—pressure diverticula, traction diverticula, and traction-pressure diverticula. These forms were discussed at length. He said that the chief value of the esophagoscope was for the removal of foreign bodies. Dr. Edward H. Ochsner exhibited some concretions which were found in a pancreatic cyst. Dr. John L. Porter discussed the diagnosis and treatment of coxa vara. Dr. D. A. K. Steele reported an interesting case of single kidney in the median line, with two ureters.

Chicago Medical Society.

At a meeting, held February 7, 1906, Dr. A. P. Heineck read a paper on "Gross Abnormalities of the Appendix Vermiformis Noted in 3,559 Post-Mortems." He drew the following conclusions: The appendix is almost always an intraperitoneal organ; exceptionally, it is extraperitoneal. It has been found in nearly every portion of the abdominal or pelvic cavities. It may form the contents or part of the contents of a hernial sac. Its presence in a hernial sac does not render it immune from the lesions to which it is subject when normally located. It may be adherent to any intraperitoneal organ or structure, or to some extraperitoneal structures, such as kidney, retrocolic cellular tissue, etc. Pathological conditions have been found which seem to indicate that inflammations can extend from it to neighboring organs and structures to which it is adherent, and *vice versa*. In diagnosing obscure abdominal and pelvic conditions, the probability of a previous or of an existing appendicitis must be considered. Pus may be present within the cavity of the appendix, within the walls of the appendix, or the condition of periappendical abscess may occur. Inflammations of the appendix may terminate in resolution, in adhesion, in obliteration, in interstitial thickening, in gangrene, ulceration, and perforation of the organ, or in suppuration. One attack of appendicitis predisposes to other attacks, until complete obliteration of the lumen of the appendix has taken place. The lodgment of foreign bodies in the lumen of the appendix is an infrequent occurrence, only two cases, excluding enteroliths, having been observed in 3,560 cases. Neoplastic disease of the appendix is uncommon. It is probable that they are almost always secondary, although some primary cases have been reported. This organ may be the seat of lesions of the same nature as can occur in other portions of the alimentary canal, viz., typhoidal, tuberculous, actinomycotic, dysenteric, etc. Tuberculous appendicitis is almost invariably secondary. The lessened frequency during the last decade of diffuse suppurative peritonitis following operations for appendicitis is due to more exact diagnosis, to earlier operation, to excision of the appendix and of its mesentery in cases not complicated by periappendical abscess, to better and more perfect technique on the part of the operator, and finally to limiting the surgical intervention in cases of periappendical abscess to incision and evacuation and drainage of the pus cavity, if the appendix be not easily accessible. Dr. Wm. J. Butler read a paper entitled "Febrile Temperatures During the First Days of Life." The author stated that abnormalities in temperature during the first days of life were frequently overlooked, owing to the lack of systematic observation with the thermometer, which alone made it possible in many cases to determine the presence of disease. The rectal temperature of the newborn averaged 37.8° C. (100° F.); it dropped one or two degrees during the first few hours, returning to 37.5° C. at the end of thirty-six hours. There was a second decline on the fourth day, followed by a rise, reaching its maximum on the eighth day. Abnormal elevation of temperature was frequent, reaching in the experience of Eross 43 per cent. That it was due to infection or toxemia was shown by the result of prophylactic measures, which reduced the percentage to 11.38. The infection might come from the birth canal or be communicated after birth; it might enter through the navel, the respiratory, or the gastrointestinal tract. The author reported four cases, constituting a small ward epidemic, with autopsy findings in one fatal case. The temperature was elevated in all, reaching 40.5° C. (105° F.) in two cases; the course of the fever was remittent, and lasted from ten to fifteen days or more. There was catarrh of the nose and pharynx, some cough, mild gastroenteritis, and in two cases a skin eruption. Restlessness, sometimes drowsiness, was not noted; occasional vomiting and irregular bowel movements occurred; the urine showed a brick-dust deposit, and in one case anuria. The cases showed that this was the result of the high temperature, rather than its cause. There was more or less discharge from the umbilicus, but the autopsy did not sustain a theory of infection through this channel. Catarrh of the bronchi was established by the autopsy, and bacterial studies indicated that this was due to the micrococcus catarrhalis and to the pneumococcus. There was decided evidence of contagion, as the infants affected were those placed in the same cot with the first case, while others in the ward escaped. Prophylaxis required aseptic treatment of the cord, avoidance of infection from the mother or attendant, and the isolation of the sick child. Treatment consisted in sponging or bathing for the high temperature, diluting the breast milk with sterile water or limewater, enteroclysis, and small doses of calomel for the gastrointestinal disturbance, water by mouth and rectum, with sodium bicarbonate in enema for the tendency to anuria, and local swabbing of the nares with boric acid solution.

State Medical Licensing Boards.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery.	Montgomery	May	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	July	2.
Arkansas*	J. P. Runyan, Little Rock	Little Rock	July	10.

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

District of Columbia allows reciprocity, but only on the following conditions: "(*a*) No applicant shall be licensed who is not of good moral character and free from mental defects and drug habits liable to interfere with the proper practice of medicine and surgery; (*b*) nor who, at the time of making application, and for not less than two years prior to the date thereof, has not been lawfully authorized to practise medicine and surgery, and actually engaged in such practice, in the jurisdiction wherein he resides; (*c*) nor unless the applicant acquired the right to practise medicine and surgery in such jurisdiction under conditions equivalent to those with which he would have had to comply in order then to have practised medicine and surgery in the District of Columbia; (*d*) nor unless the jurisdiction, by virtue of whose license the applicant seeks exemption from examination in the District of Columbia, grants to licentiates of the Board of Medical Supervisors of said District privileges equivalent to those which the applicant seeks; (*e*) nor until the applicant has paid to the Board of Medical Supervisors aforesaid such fee as may be fixed and required by the regulations of said Board, but not more than the fee charged under similar circumstances by the jurisdiction by virtue of whose license the applicant seeks exemption from examination."

New Jersey.—The medical license of New Jersey is indorsed, at this time, in lieu of further examination, by Maine, New York, Vermont, Delaware, Virginia, South Carolina, Texas, Ohio, Illinois, Michigan, Minnesota, Wisconsin, Kansas, and Colorado. New Jersey will indorse the medical license issued by any State after examination, whose educational, examining, and licensing those of New Jersey, irrespective of reciprocity, provided the applicant complies with the conditions of requirements are substantially equal to, or higher than, indorsement.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cas and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 21, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	375	188
Diphtheria	312	58
Measles	1566	46
Scarlet Fever	212	18
Smallpox	2	.....
Varicella	138	.....
Typhoid Fever	23	7
Whooping Cough	33	1
Cerebrospinal Meningitis	48	29
Malarial Fever	.....	.....
Totals	2,709	347

Spontaneous Disappearance of Moles.—Dr. L. Spitzer describes a large verrucose pigmented mole present from birth upon the thigh of a man 24 years old. At the age of 4 years it began to disappear, shrinking at its lower part and gradually disappearing from below upward, the black hairs falling as the warty parts receded. He mentions a similar instance reported by Lassar in 1895. Here, however, the gradual shrinkage occurred during a five weeks' course of Fowler's solution.—*Dermatologische Zeitschrift.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Puhlic Health and Marine Hospital Service for the week ending April 21, 1906:

A CASE OF HETEROPLASTIC OVARIAN GRAFTING, FOLLOWED BY PREGNANCY, AND THE DELIVERY OF A LIVING CHILD.*

By ROBERT T. MORRIS, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE; MEMBER OF THE AMERICAN MEDICAL ASSOCIATION, ETC.

Mrs. H. W. was sent to me at the Post-Graduate Hospital by her physician, Dr. H. L. Barker of Woodside, New York, on February 1, 1902. She was 21 years of age, began menstruating at 15, and stopped menstruating at 19. Previous to the cessation of menstruation the function had been of average character. She was married at the age of 18, became pregnant soon after, and had a miscarriage at the third month. During the two years previous to her entrance into the Post-Graduate Hospital she had suffered from the common menopause symptoms of pelvic pain, headache, and hot and cold flashes. These symptoms had steadily increased in intensity, and were most marked at the times when the monthly flow should have appeared.

I made a diagnosis of cirrhotic ovaritis and asked the patient to remain in the hospital until an opportunity presented for obtaining ovarian grafts from some other patient, to replace her own ovaries, which were to be removed. A week later Mrs. W. was prepared for operation, but as I did not quite like the character of the ovaries from which grafts were to be taken, the patient was asked to wait for a better choice. On February 11, 1902, Dr. H. J. Boldt had occasion to operate upon Mrs. G. P. for uterine prolapse. Mrs. P. was 33 years of age, and the mother of three children. Her ovaries were normal excepting for the congestion common to prolapse cases. While Dr. Boldt was operating I removed from Mrs. P. ovarian tissue in the form of a wedge-shaped ribbon, not quite as much as usual in my experimental work, but enough to be incidentally beneficial in relieving the congestion for Mrs. P. at the same time that grafts were obtained for Mrs. W. The grafts were placed in physiological saline solution at a temperature of 100° Fahrenheit, and maintained at the temperature by a nurse until the abdomen of Mrs. W. had been opened through a short median incision. (It is important in dealing with delicate structures to choose the saline solution, which is isotonic with human blood.)

The ovaries of Mrs. W. were removed with Tuffier's angiotribe. The reason for choosing this method is because the ligation methods are apt to be incomplete in assuring absolute removal of all ovarian tissue. When the broad blades of the angiotribe close upon the pedicle of the ovary, the ovary is crowded away from its seat and rises above the blades, thereby avoiding the possibility of leaving ovarian tissue behind. I have been particular in developing this point of technique in ovarian grafting, and in our experimental work with rabbits, my associate, Dr. L. A. di Zerega, has insisted that we must not allow even a particle of scraping from an excised ovary to fall back into the peritoneal cavity, because a single detached ovum might live in contact with the peritoneum long enough to invalidate the experiment. After removal of each ovary of Mrs. P., a slit was made through the peritoneum of the broad ligament on either side, parallel with the oviduct, and dorsad from the original seat of the ovary. Into each slit was placed a segment of ovary from Mrs. P., about one-half inch long, and one-fourth inch wide. A single catgut suture was placed in such a way as to hold each graft in place. Grafts are so placed that the cut surface of the ovary lies in contact with the cut surface of the broad ligament, in order that the nutrition of the graft may be maintained through the lymph circulation, pending the formation of new capillaries. Uncut surface of ovary is allowed to project into the free peritoneal cavity, to facilitate the free escape of ova. The uterus and oviducts of Mrs. W. were apparently normal. The ovaries removed from Mrs. W. were given to Dr. H. T. Brooks for microscopical examination, and he reported later that they were cirrhotic ovaries, distended with many small cysts, and containing no formed Graafian vesicles. Mrs. W. and Mrs. P. made customary recoveries from their operations.

Present at the operation upon Mrs. W. were Dr. H. J. Boldt of New York, and the hospital staff assistants, Dr. R. G. Treacy, now of New Haven, Conn.; Dr. W. H. Allee, now of Stamford, Conn., and Dr. D. W. Cairns, now of New York.

On July 1, 1902, I received a letter from Dr. H. L. Barker, stating that for about a month after Mrs. W. returned from the hospital she felt well excepting for a continuance of the hot and cold flashes. On June 18, 1902, four months after the grafting, Dr. Barker wrote that Mrs. W. had at that date menstruated, menstruation lasting for five days. (Grafted patients have usually first menstruated at periods varying from two months to five months after the operation.)

On March 28 of the following year (1903) Dr. Barker again wrote, stating that he had just seen Mrs. W. and obtained the following history: After the menstruation of June, 1902, she did not again menstruate until November 16 of the same year, when she flowed for one day. The next month, December 15, she flowed for four days, and menstruation after that became regular, with a flow for four or five days at each period. The patient was "feeling perfectly well and happy."

Nothing more was heard from Mrs. W. until March 28 of the present year (1906), when I received a letter from Dr. Robert Lount of Hempstead, N. Y., stating that he had under his care a patient by the name of Mrs. H. W., who informed him that she was one of my ovarian grafting pa-

*A paper read at the meeting of the Surgical Section of the New York Academy of Medicine, April 6, 1906.

tients. He had on March 15, 1906, delivered her of a daughter weighing seven and one-half pounds, and mother and daughter were doing well, excepting for some manageable complications on the part of the mother. On April 4 I received a subsequent letter, stating that mother and daughter were doing well, and that the mother had a good flow of milk.

On April 14 I received a letter from Dr. H. L. Barker stating that he had examined Mrs. W. when she was about four months pregnant, but on account of her distance from his circuit of practice he had depended upon others for her care at parturition.

So far as I can judge we have in this case a well-defined instance of heteroplastic ovarian grafting, followed by pregnancy, and the delivery of a normal child. If the pregnancy had appeared in one of my earlier grafting cases, when the ligature method for removal of ovaries was employed, I might have been a trifle skeptical about the nature of the case, but this pregnancy occurred after the adoption of a technique which was, to my mind, satisfactory in eliminating any weak points in our work.

Through all of the varying ideas on the subject of ovarian grafting during the past few years I have felt that some one would eventually get a child out of some case of homoplastic grafting, as our experiments upon rabbits and other animals seemed to show that when the ovary of an animal was removed from the body, and then reintroduced in its original host, there was a tendency for the ovary to live, and to continue its function. When, on the other hand, ovary was grafted from one animal into another, the principle of intolerance of the tissues of one animal for the tissues of another animal came into play, and there was a tendency for the grafted ovary to degenerate or to become absorbed. It was noted, however, that there were various degrees of tolerance shown, and this seems to be an important point. One animal would absorb the ovaries of another animal very rapidly, while a third animal might carry the ovaries of a fourth for several months. In the case of Mrs. W. it is probable that we have an instance of tolerance for the tissues of Mrs. P. that may have amounted to complete tolerance. It is important for us to experiment along lines which will allow us to prepare animals for tolerating the tissues of each other, and I had planned to do this work, but in the midst of active practical professional work experiments go along slowly, and at the present moment I have material collected for an experiment in another field entirely, and which will demand every hour of spare time for a year at least.

At Cornell University Medical Laboratory I carried on one line of experiments, suggested by the known principles of hemolysis, with the assistance of Dr. James Ewing, Dr. George H. Ryder, and medical students, Messrs. E. D. Watkins, W. E. Drennan, and R. E. Pou. A series of rabbits were made immune to each other's serum, and their ovaries were then exchanged. These ovaries, as anticipated, were absorbed more rapidly than in animals not immune to each other's serum, but I wished simply to get the facts, in order to make use of the negative testimony.

In women I have, up to the present time, done homoplastic and heteroplastic ovarian grafting in fourteen cases, and in one case made a homoplastic graft of the fimbriated extremity of an oviduct in a case of fibronodular oviduct. The fimbriated end was fastened to the cornu of the uterus after excision of the nodular area, which included nearly all of the tube.

So far as I know there has been but one other case of conception among my grafted patients. This was in a case of homoplastic ovarian grafting, and the patient had a miscarriage at the third month. The case was not properly safeguarded for scientific report, and I have said little about it, and have not asked the profession to accept the testimony, but personally there is to my mind no reason for doubting the statements of the patient herself. I expect much of homoplastic grafting, but had about given up hope of obtaining pregnancy in heteroplastic grafting cases until we could prevent patients from absorbing the grafted ovary, and this case of the child of Mrs. W. came to me as a surprise. My efforts had turned toward perfecting methods for homoplastic grafting, for the purpose of avoiding the precipitate menopause, retaining the influence of the internal secretion of the ovary, and the normal sexual attitude of the patient, in selected cases in which for any reason both ovaries had to be removed. There seemed also to be a fair probability that pregnancy might sometimes occur.

The present case of heteroplastic grafting renews our hope that we may make fertile some women who have reached the menopause through disease, surgical operation, or possibly after the normal menopause.

It will be interesting to note which parent the child of Mrs. W. most resembles. According to Haeckel hereditary characteristics are due to cell memory, and the cell memory of an engrafted ovary may not be changed by the influence of its new host. It is fair to say, however, that the mother who bore the child is the real mother, as she furnished the nutrition for development of the child. It is somewhat important, aside from medical and from ordinary sociological interest, to place the status of this child, for in legal circles the word "descendants" will now come to have a larger meaning.

Concerning the matter of priority in this field of ovarian grafting, according to the *Index Medicus* the proposition of the idea, the description of the technique, and the report of cases were published in New York in the year 1895. The papers of Chrobak and of Knauer followed in 1896.

Note.—A number of physicians with whom I have discussed the ovarian grafting case, state that they are sure that the ovaries were completely removed in cases in which menstruation continued. Questioning elicits the statement that such ovaries were removed by ligation methods, and that any portion of ovary remaining must have been "outside of the ligature, where it could receive no nutrition." This is the very point that is brought out in my experimental work in homoplastic grafting. A trifle of ovary outside of the ligature may receive enough lymph circulation by peritoneal contact to insure vitality, and it then becomes a homoplastic graft. A few cases of pregnancy have been reported in cases in which the ovaries were believed to have been removed. I think that these are, in fact, homoplastic graft pregnancies, and that they offer testimony in support of the theory that such pregnancies can occur readily enough if the oviducts are in condition to allow it. It is a question if menstruation can occur without the influence upon the uterine ganglia of the internal secretion of that temporary organ, the corpus luteum. The employment of Tuffier's angiotribe or of methods of complete excision of the ovary, followed by suture instead of ligation, will insure complete removal of all ovarian tissue. I do not remember to have had menstruation follow in any case in which either one of these methods was employed, unless grafts had been placed in the patient purposely.

616 Madison Avenue.

THE PRACTICAL SIGNIFICANCE OF OUR KNOWLEDGE OF BACTERIA IN THEIR RELATION TO PNEUMONIA.*

By AUGUSTUS WADSWORTH, M.D.,

NEW YORK.

ALONZO CLARK SCHOLAR IN PATHOLOGY; INSTRUCTOR IN BACTERIOLOGY AND HYGIENE, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; ASSISTANT PHYSICIAN TO THE ROOSEVELT HOSPITAL OUT-PATIENT DEPARTMENT.

In the short time at my disposal this evening, I shall outline, briefly, in a suggestive way the points of practical significance, which may be gleaned from our knowledge of bacteria in their relation to pneumonia.

It is hardly necessary to review the early work, now chiefly of historic interest, which has led up to our present knowledge of the bacterial incitants of pneumonia. Suffice it to note in passing, that from bacterial examination of the pneumonic lung at autopsy, in long series of cases, it is now generally recognized: that the pneumococcus, streptococcus, staphylococcus, the bacillus of Friedlander, and possibly the influenza bacillus, are the most important of the incitants of the disease; that the lobar type of pneumonia is practically a specific pneumococcus infection; that the bronchial or patchy lesions are also in most instances, especially the primary infections, incited by the pneumococcus; but that in some localities, and particularly in the secondary pneumonias following the exanthemata, the streptococcus has been found with great regularity. The tubercle bacillus occasionally found in these acute pneumonic processes is doubtless a mark of secondary infection; and the presence of the influenza and Friedlander organisms may be similarly explained in many, not all, cases. The pneumococcus thus occupies a position of prime and, barring the streptococcus, almost exclusive importance.

The methods of demonstrating and differentiating these bacterial incitants of pneumonia, have recently been greatly simplified by the work of Hiss. Capsules may now easily be demonstrated on pneumococci and pneumobacilli. Morphologically the pneumobacilli occasionally resemble the pneumococci, but with the Gram stain they decolorize, and in culture the luxuriant slimy growth of the Friedlander bacillus may usually be distinguished at a glance. Hiss, by his more precise methods of staining, found that the streptococci occasionally show capsules and that the pneumococci may fail to develop them. Cultural tests thus proved to be the surer guide to an accurate differentiation; of these the fermentation of the carbohydrate inulin by the pneumococcus proved the most constant.

By bacterial examination of material from cases of pneumonia, the presence of these species of bacteria may often be readily determined. The presence of the tubercle bacillus is usually of precise diagnostic significance, and the finding of the incitants of the acute pneumonic processes in the blood or in exudates of the body tissues is similarly significant, but in the secretions of the mouth, pneumococci and streptococci are frequently found under normal conditions.

The distribution and dissemination of both pneumococci and streptococci in different communities is well shown by a great variety of researches, the discussion of which is necessarily curtailed in this short presentation of the subject. In the mouths of healthy persons various streptococci, which at present cannot be accurately differentiated, have been found with great regularity. Pneumococci, corresponding to those found in pneumonic lesions, have also been demonstrated in the mouths of many apparently healthy people. The percentages given by different observers vary from 4 to 100 per cent., and average between 25 and 35 per cent. Crowded and densely-populated districts, as a rule, yield the highest percentages; among them the City of New York, as shown by the recent report of the Commission to investigate the respiratory diseases. The sputa of persons having previously, and especially recently, recovered from pneumonia, much more frequently contain pneumococci. Netter's results gave the proportion of four out of five, as compared with one out of five obtained in normal cases. In sputum outside the body, whether dried, pulverized, or exposed to cold, the older researches indicate an exceptional viability; but these observations may be questioned, for the pneumococcus, even on the favorable laboratory media, is an extremely delicate organism, often dying after a few days' incubation at the body temperature. Recently, Wood, with improved technic has shown that in direct and even in diffused sunlight, the organisms die very rapidly, and especially when sprayed in very fine particles of sputum; but in the cold and in the dark, the pneumococcus will live for longer periods, as was found in the older researches. Finally, it is significant that both pneumococci and streptococci have been found with great regularity in pathological conditions of the pharynx, nose, and ear.

By the simple acts of speaking and whispering, to say nothing of coughing and sneezing, large numbers of bacteria are sprayed out into the air, and carried by convection currents long distances. In this way the infectious material is transferred from one person to another. During quiet respiration, practically all the bacteria inhaled are deposited on the mucous membranes of the upper respiratory tract, for the expired air is sterile. These bacteria, especially in forced inspirations, as shown by animal experimentation, sooner or later reach the alveoli of the lung. The great majority, of course, disappear, and so rapidly and completely that the lower portions of the respiratory tract are usually free from bacteria. It is only such pathogenic bacteria as have attained considerable virulence or adaptation that develop and incite varying grades of tissue reaction in the course of their elimination. The filtration of bacteria from the air, by constant respirations of the occupants of a crowded, but quiet room, may occasionally be shown by comparative bacterial examinations. But usually there is an increase, owing to the large number kicked up in the dust and sprayed out in speaking and coughing. This is often especially marked because bacteria settle on the floor and flat surfaces of the furniture in the rooms during the quiet hours to such an extent that the air may be practically free from bacteria before it is used.

Such are the data which may be cited to prove that in the distribution and dissemination of the bacterial incitants of pneumonia there is a constant and vicious cycle, the effects of which are in various ways manifested. Small epidemics of pneumococcal infection, arising in families or small communities, can doubtless be recalled by every one in active practice, and many have been recorded. That such epidemics, developing in very susceptible people in close association, may reach grave proportions, is well shown in

*Read before the Brooklyn Pathological Society, February 8, 1906.

the report, by Brodie, Rogers, and Hamilton, of an epidemic, characterized by rhinitis, meningitis, and pneumonitis, all pneumococcus infections, arising in a body of Kaffir miners. Some 12 per cent. of these miners were constantly sick, and 5 per cent. of the total number died. Streptococcus pneumonias, it has been shown, also occur in small epidemics. Influenzas and other secondary pneumonias appear in groups of cases, in some places incited by the streptococcus, in others by the pneumococcus. Both streptococcus and pneumococcus pneumonias occasionally develop in the hospital wards.

The prevalence of pneumonia during the winter months was formerly attributed to the action of cold as a predisposing factor in the development of the infection. But experience has since shown that this is a minor factor. The varying increase of cases, regularly attaining its maximum in the spring, long after the coldest weather, and abating only as summer comes, is due, not to exposure to cold, but to the huddling together of people in narrow quarters. Under these conditions, not only is the transfer of infectious material from one person to another greatly facilitated, but its quantity and virulence increase in geometrical ratio during the long winter season. Although there are many cooperating factors in bringing this about, attention may be directed especially to the fact that overheated houses, modes of life, and sudden variations of climatic changes, aside from effecting in individuals changes which directly predispose to pneumonia, favor the development of minor infections of the respiratory tract, which in turn increase, not only the amount of the infectious material, but its virulence. In New York, under these most favorable conditions, pneumonia has been increasing at an alarming rate, not only in the number, but in the gravity of the cases.

Whereas, complete and suggestive data concerning not only the infectious nature, but the communicability of pneumonia exist, no serious application has been made of this knowledge in the prophylaxis of the disease. Evidently knowledge, in this instance, has bred a costly contempt. And this here in New York, where there is every indication that immediate results might be expected from precautions as simple and rational as are taken against other less serious infections about which comparatively little is definitely known. That sanitary regulations of crowded districts, of public buildings and conveyances, which common decency, apart from any question of pneumonia, will soon demand, would alone accomplish definite results, is shown by the changes effected in the summer season by the free open life. But the secretions of the mouth constitute the chief, if not the only, source of respiratory infection, and the transfer of the infectious material takes place largely from one person directly to another. Thus the precautions and regulations within the jurisdiction of the health authorities, so successfully adopted with typhoid and similar infections, are obviously inadequate, and the responsible burden of alleviating or controlling the spread of the respiratory diseases rests largely upon the individual.

Fortunate it is that, as compared with other races of men, and particularly with the lower animals, we are relatively insusceptible. But still more fortunate is it that for the development of pneumonia certain conditions of susceptibility are essential. In the development of infection there are two chief, or, if you like, opposing, factors to be considered: the bacterial cells and the body cells. The disease processes, whether considered anatomically or symptomatically, are simply the reactions of the body cells in the presence of the infectious material. In the course of this reaction there is, on the one hand, an adaptation of the body cells to the bacteria and their products, by which varying grades of immunity are acquired; and on the other, there is also an adaptation of the bacterial cells to the body tissues, by which the virulence may be increased or altered. Owing to the marked susceptibility of certain animals to pneumococcus inoculation and the varying grades of insusceptibility that may be secured by specific immunization—offering, as they do, complete analogies to the varying grades of susceptibility observed in man—the experimental study of pneumonic infection has proved exceptionally significant. The results of these researches have already, in a former paper, been considered in extenso. But briefly, it was found that virulent bacteria, whether introduced directly into the circulation or through the tracheæ of very susceptible animals, incite rapidly fatal general infections without local lesions; but, when injected through the tracheæ of only moderately susceptible animals, bronchopneumonic types of lung lesion are incited. The diffuse lobar types of lesion were secured only in animals relatively insusceptible, and only by the introduction through the tracheæ of such bacteria as possess or quickly attain an exalted virulence. Thus, by varying the susceptibility of the animal by predisposition or immunization, and the virulence of the bacteria by passage through the species experimented upon, it was shown that in animals and in man, essentially similar etiological conditions in slightly varying relationship give rise to slightly varying lesions, differing only in type.

The tissues of the lung are especially well adapted for the absorption and elimination of noxious substances, and thus in a measure protect the body from the development of systemic infection. Apart from this the marked protective resources of the body systemically and the virulence of the pneumococci are very delicately and evenly balanced in lobar pneumonia. The extremely virulent pneumococci rapidly develop in the accumulating exudates of the lung. This development sooner or later involves the general system as a bacteriemia which, as is well shown by the results of bacterial examination of the blood, is a frequent, if not a constant, feature of the disease. In the course of the lung infection, the development of the bacteria, at first in the ascendant, is subsequently inhibited and the bacteria in the exudate are so rapidly disposed of that even in fatal cases of the pure pneumococcal infections the exudate, which in early lesions, contains numerous cocci, is comparatively free from bacteria in the later stages. This, apparently, is a peculiarity of the lobar pneumococcus infections, for it is not found in the so-called Friedlander pneumonias. It is, therefore, significant to recall the peculiarly marked susceptibility of the pneumococcus to unfavorable conditions. In cultures, Fraenkel found that the organism lost its virulence after twenty-four hours' exposure to 42° C., and after 6 days at 41° C. Its susceptibility to osmosis is similarly marked. For example, Neufeld found that a drop of normal rabbit's bile sufficed to bring about the complete dissolution of the pneumococci in 1 c.c. of broth culture; and the comparatively rapid autolysis which pneumococcus

cultures undergo after the growth has reached its maximum is well known. Thus, it may be suggested that owing to the marked insusceptibility of the lung tissues, their great capacity for adaptation and the apparently marked susceptibility of the pneumococcus to these unfavorable conditions, the reactive processes of the lung tissues in lobar pneumonia, are seemingly able to cope with the infectious material lying in the air spaces theoretically outside the body. And also that although the lung reactions constitute the most obvious feature of the infection, this is but part of the disease as a whole, and, possibly, from the standpoint of recovery, a minor part.

By further researches on the recovery of susceptible and immunized animals from pneumonic infection, it has been possible, not only to confirm the suggestive findings in fatal human cases, but to secure a termination of the infection approximating the crisis in man, and thus complete the analogies of recovery. The results of these studies are reasonably complete, although they have not, as yet, been published. Briefly, it was found that the pneumonic crisis in animals is accompanied by a peculiarly extensive dissolution of the pneumococci throughout the body, and apparently coincident with the fall in temperature. This did not occur in the fatal infections, or in those recovering by lysis. A similarly extensive dissolution of the pneumococci during the human crisis obviously cannot be so precisely established. However, the marked disappearance of the cocci from the exudate, even in fatal cases, the very rare occurrence of abscess, gangrene, or complicating conditions in the lobar lesions of pure pneumococcus infections, and the exceptional development of complications after crisis as compared with their prevalence in lysis and in fatal infections, and, finally, the failure to find pneumococci in the lung by thoracentesis after the crisis, when they are so regularly present before, may reasonably be considered significant.

In forecasting the results of the struggle between the two opposing factors of infection—the body cells and the bacterial cells—so evenly balanced in lobar pneumonia, there are obviously serious difficulties, and it is hardly necessary to review, in detail, the various attempts to secure some sign, admitting of precise determination, upon which a prognosis may be safely based. Suffice it, therefore, to outline briefly the results of this study. The prognosis is primarily dependent upon the generalization of the infection and its subsequent localization, but is only very inadequately suggested by the presence of bacteria in the blood, for this condition also occurs frequently in favorable cases. The age and the habits of the patient have proved to be, in general, exceedingly important factors; but in particular cases, these are often of doubtful significance. Similarly, an extensive involvement of the lung is a sign, not only of a virulent infection, but of a marked capacity for recuperation in the patient. Slight lung lesions are indicative of mild as well as of extremely virulent infections; and thus in infants and old people, whose susceptibility is great, such pneumonias are often serious. Certain of the changes occurring in the blood have been considered significant. A constantly high leucocytosis is a favorable sign and a low count unfavorable; but in individual cases a low leucocytosis may be due to a mild infection, and the high count to a virulent infection. The return of the eosinophiles, which, during the active stage of the disease, disappear or are greatly diminished in number, has been taken for a sign of the crisis; but this has not, as yet, been fully determined. The agglutination reaction is of some diagnostic value in obscure cases of pneumonia; but a careful study of fifty cases in my experience failed to reveal any definite prognostic suggestions.

The clinical picture of the disease from day to day thus constitutes the court of last resort for the correct interpretation of these extremely valuable, but uncertain, determinations in the prognosis of the individual case.

In the attempt to bring to a favorable issue this struggle between the body cells and the bacterial cells, there are obviously serious difficulties, which, now that they are being more fully realized, render seemingly ridiculous the heroic efforts of older observers to abort or control the course of pneumonia by the use of such drugs as tartar emetic, quinine and other antipyretics, veratrum viride, digitalis, and, last, but not least, ergot, for it is still being feebly advocated by some observers. In the light of this valuable, but costly, experience, the reasons for the adoption, and the long discussions leading up to the judicious withdrawal, of one after another of these powerful drugs, are now only of historic interest.

Victor Hugo defined composition as the art of putting the right word in the right place, and Millet similarly described painting as the art of putting the right color in the right place. The administration of drugs and treatment is an art. In malaria, quinine; in syphilis, mercury; in diphtheria, antitoxin, act specifically; but in pneumonia the right drug has not, as yet, been determined. Pneumonic infection varies in different localities, and at different times, to such an extent that the comparative study of different modes of treatment is extremely difficult and at best uncertain. Such statistics as include long series of cases for several years, however, suggest that the simpler measures, in the old days as now, yield, all things considered, the best results. Northrup has done a great service here in New York by calling attention away from the vagaries of the past and directing it to the open window. But aside from these obvious, yet much disregarded, indications for simple, nutritious diet, for cool, fresh, unpolluted air, sunlight, the requisite amount and kind of clothing, and for quiet—aside from all this, conditions arise in the individual cases of pneumonia, as in those of other infectious diseases, which require active measures, however inadequate they may be, in controlling the development and course of the infectious disease.

Of first importance is a careful prophylaxis against disturbances of the digestive tract. Except in rare instances, when both lungs are mechanically blocked, the respiratory organs, in spite of the lung involvement, are comparatively free from serious functional derangement, until the circulation fails, and this steadily, even in favorable cases, weakens as a result of the continued fever and the prolonged toxemia. It is hardly necessary in this brief and purely suggestive outline of the subject to consider, in detail, possible or even probable contingencies, and the means at our disposal for their relief. Suffice it to recall the importance of determining accurately the changes occurring in the individual cases before resorting to venesection or saline infusions, to ice packs or baths, to stimulation with alcohol and powerful drugs, or to other strenuous measures which have apparently proved of great value in

certain cases, but which in most instances are ill-advised and liable to do serious damage. Thus it is that in the treatment of pneumonia there is a more and more precise realization of the limitations and of the difficulties of avoiding, on the one hand, the pitfalls of over treatment, and, on the other, of rendering efficient aid to the natural resources of the body tissues upon whose capacity for adaptation recovery ultimately depends.

There are many ways of achieving the same end, and the choice rests largely, if not wholly, with personal experience; the experience of one is not necessarily that of another, nor is it ever a final criterion. And thus the treatment of pneumonia in its present stage, like the poetry of Hugo, to use the author's own words, is very easy or it is impossible.

The hope of definite results in the treatment of pneumonia lies in the production of an efficient and specific antiserum. Certain it is that poisonous substances are elaborated by the pneumococcus; but the attempts to secure from this organism, under artificial cultivation, a sufficiently concentrated toxin, which in animals would give rise to a corresponding antitoxin similar to that now used in diphtheria, have failed. Diphtheria, however, is essentially a toxemic disease, in contradistinction to the bacteremic, in which the incitants develop, not only in the local lesions, but in the circulating blood, as in pneumonia. Antisera which act on the bacterial cells have been secured in sufficient strength to control many of the infections in smaller animals, but in none of the bacteremic diseases of man have satisfactory results, as yet, been secured.

Since in lobar pneumonia the protective resources of the body tissues are so extremely well adapted for the elimination of the infectious material, and since the pneumococcus, as compared with other pathogenic bacteria is extremely susceptible to unfavorable conditions, the hope of success ultimately crowning failure brightens, materially, with each new advance in our knowledge of pneumonic infection.

A CASE OF SYRINGOMYELIA WITH PARTIAL MACROSOMIA.

By M. G. SCHLAPP, M.D.,

NEW YORK.

CHIEF OF CLINIC FOR NERVOUS AND MENTAL DISEASES, PRESBYTERIAN HOSPITAL; INSTRUCTOR IN NEUROPATHOLOGY, CORNELL UNIVERSITY MEDICAL COLLEGE.

Not many years ago, cases showing hypertrophy of one or more extremities, or other parts of the body, in connection with symptoms of syringomeylia, were described as acromegalia with accidental association of syringomeylia. These two groups of symptoms were looked upon as not having any special relationship to each other. It was not until recent years that this combination of symptoms was recognized as being caused by the same lesion, syringomyelia. This condition has been given a special name by Schlesinger—"Partial Macrosomia." For the enlargement of the whole hand, Hoffman and Marie have chosen the name "Cheiromegalia;" for the enlargement of the foot, Schlesinger has suggested the name "Podomegalia."

This hypertrophy usually begins in one extremity, spreading from there to the trunk, or jumping to the other extremity. It seems, sometimes, to involve the soft tissue alone; other times, and less frequently, it involves the soft and skeletal tissues. The length of an extremity is not found increased as often as is the thickness, nor does the length increase as much, when increased at all, as does the thickness.

In connection with the hypertrophy of the tissue, arthropathies are frequently found—thickening of bones about the joints, hardening of articular ligaments, and, as in the case described by Nolbandoff, softening of the bones.

The following case shows the unusual and interesting combination of hypertrophy of an extremity with dissociation of sensation, and with a number of other interesting symptoms.

G. H., male, thirty-eight years old, married, and has four healthy children. Father died of old age. Mother living and well, eighty-three years old. Three brothers and two sisters living and well. Two brothers died in infancy, cause not known.

Family history negative as to tuberculosis, nervous or mental diseases, rheumatism, etc. No deformities in family. As a child and boy, the patient always enjoyed good health. Fifteen years ago he had chancre with marked enlargement of the inguinal glands, which were very painful. He never had any further trouble from the chancre, but states that his wife had two miscarriages, and that one child died a few hours after birth.

The habits of the patient are good. Up to two years ago he was well. At this time he began to feel a heaviness in his left shoulder, and somewhat in the left arm. He paid no further attention to this condition until last December, about Christmas time, when rather suddenly his legs gave way, he felt "ill all over," as he expresses it, and went to bed. Immediately after this attack of indefinite illness, his left shoulder, arm and hand began to swell to about twice their normal size. He had no pain in the swollen arm and hand, but some in the joints of the right arm and hand. The arm remained swollen for about two or three months, after which the swelling began to subside gradually. Since this illness it has always been somewhat larger than the right arm and hand. Immediately after the onset of the illness in December, patient began to have attacks of dizziness, and during some of these attacks, he would become totally blind in his left eye, the loss of vision lasting for about five minutes. These attacks of total blindness occurred four times, successive days. After the fourth attack the blindness was not complete. The loss of sight was confined to the lower half of the visual field; only the upper half of the left retina being involved. These attacks of partial blindness of the left eye gradually became less frequent, until now they occur about once a week, or once in ten days, accompanied always by dizziness.

During the past summer patient noticed that, while during the hot weather the right side of his face would perspire very freely, the left side would always remain dry. He was not so sure about the absence of perspiration on the left arm and chest, although he thinks they do not perspire so much as the right.

Status præsens: Well nourished man, not much adipose tissue, but muscles well developed. Symmetry of face not disturbed, except that the left eye is drawn back into the fossa somewhat more than the right, which, however, does not show well in the photograph.

The left scapula has a lower position than the

right, and recedes more from the vertebral column.

The left half of the chest and back, the left arm, and hand are larger than the right chest, arm, and hand. This is clearly seen in the accompanying illustrations (Figs. 1 and 2), drawn from photographs.

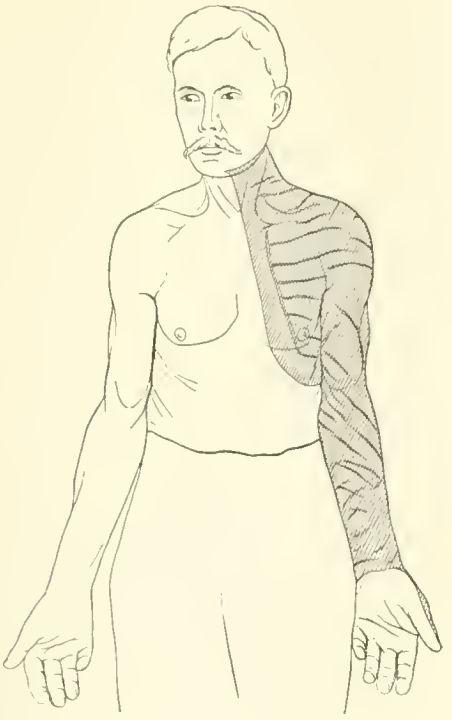

Fig. 1.—Anterior view.

There is a slight double curvature of the spine; the upper convexity in the region of the sixth and seventh cervical vertebræ pointing to the left, the lower convexity at about the fifth, sixth,

Fig. 2.—Posterior view.

and seventh dorsal vertebræ, pointing to the right. The lower part of the body and the legs appear normal.

The measurement of the two arms, and both sides of the body in the region of the chest are as follows: Middle of biceps, R., 28 cm.; L., 30 cm. Over largest circumference of lower arm, about 1½ inches below the elbow joint, R., 27 cm.; L., 28 cm. Wrist, over prominence, R., 18½ cm.; L., 20 cm. Hands, with thumb adducted, at base of first phalanx of thumb, R., 25 cm.; L., 26 cm. Over base of first phalanges of hands, thumb abducted, R., 22½ cm.; L., 23 cm. Length of middle fingers from base to tip, R., 11 cm.; L., 11½ cm. Length of ring finger, R., 10 cm.; L., 10½cm. Length of little finger, R., 8 cm.; L., 8½cm. Chest, from spine to middle of sternum over the nipple, R., 45 cm.; L., 46½ cm.

There is complete loss to the pain and thermal senses over the whole of left arm and hand, and on the surface of back and chest, neck, and back of head, as indicated by the shading in the illustrations.

On the chest, the area in which the thermal sense is lost is smaller than the area of analgesia, as indicated by the second line. Tactile and muscular senses not disturbed. No sensory disturbance in the trigeminal region, or on any other part of the body. The skin reflexes are present. The tendon reflexes of the legs, right arm, and jaw are slightly exaggerated. Tendon reflexes of the left arm are very much diminished.

The patient was placed in a hot air chamber and allowed to perspire freely. It was seen that on the left side of the face there was no perspiration (anidrosis), whereas, on the right side there was profuse perspiration, the line of demarcation being sharply drawn down the middle of the face. The left arm and hand, the left side of chest and back were moist, whereas on the right side, on the same areas, the perspiration was very profuse.

The bones of the left wrist joint seem enlarged. There is a permanent dislocation of the carpometacarpal joint of the thumb, which cannot be replaced. This dislocation is readily seen in the *x*-ray picture.

The strength in both arms and hands is equal, but in comparison to the muscular development the strength seems to be diminished. Both hands register 80 on the dynomometer. Nowhere is there seen any muscular atrophy or paralysis. A paresis of the left *rhomboidei* and *levator anguli scapulæ*, however, is found

Eyes: pupils equal; react to light and accommodation. Movements of the eyes normal. Visual field normal; normal fundus; physiological excavation of the papilla; left eye cleft smaller than right; left eye deeper in fossa than the right (enophthalmus)

Lungs: Normal.

Heart: Somewhat enlarged Loud systlioc murmur heard at apex, transmitted to all parts of the left chest. Mitral insufficiency. Blood pressure equal in both arms, measuring 120 mm. at systole, and 83 mm. at diastole.

Skin temperature equal on both sides. All other organs apparently normal. Taste, smell, and hearing normal

For a year previous to the acute attack which the patient had in December of 1904, his left arm felt numb and not the same as did his right arm, although he did not know that the pain and thermal senses were absent until the examination was made at the clinic. It seems probable, therefore, that the loss of the pain and thermal senses has been gradually coming on for at least one year previous to the acute attack. This attack was, no doubt, brought on by a hemorrhage in the area of gliosis, or in the necrotic tissue, the result of a central gliosis (for such I take the lesion to be).¹ It would appear that

the hemorrhage confined itself to the intermediate gray matter at the base of the left anterior horn throughout a number of segments, first cervical to about the sixth dorsal. Two sets of symptoms resulted from this hemorrhage: irritative and paralytic.

As irritative symptoms, must be considered the attacks of blindness of the left eye, and, with this blindness, the dizziness. These attacks were no doubt caused by an irritation to the sympathetic centers in the cervical region, causing spasms of the blood-vessels of the left retina, with resulting blindness, and spasms of the small vessels in part of the brain, with resulting dizziness.

These irritative symptoms have gradually subsided since the onset of the acute attack. An interesting feature to which attention should be directed, is that when the irritation was most marked, all the blood-vessels of the retina were involved in the spasm, but as the irritation subsided the spasm involved only the blood-vessels of the upper half of the retina. The correct interpretation of this peculiar phenomenon is, no doubt, that the motor impulses from the intermediate gray matter of the cord passing through the cervical sympathetic to the upper half of the eye, come from cells that have a different position from that of those cells which supply the blood-vessels of the lower half of the retina.

With the paralytic symptoms must be classed the anidrosis of the left side of the head, the enophthalmus (paralysis of M. orbitalis), and the edema of the hand, arm, and shoulder, caused by the paralytic dilatation of the blood-vessels in these parts. It is very probable, likewise, that an enlargement of the area of analgesia and loss of the thermal sense took place after the hemorrhage, although this could not be demonstrated, as it is impossible to know how large the area was in which the pain and thermal senses were missing before the acute attack.

Before the appearance of the edema in the left arm and shoulder, the patient is positive that there was no difference in the size of both arms. It seems, therefore, that the hypertrophy began to develop some time during the existence of the edema. This being the case, is there any connection between the edema and the subsequent hypertrophy? I am inclined to think that there is, although it would have been desirable and important to know whether all tissues were involved in the process of hypertrophy, or whether there is only increase in the connective tissue as the result of katabiotic changes. I suggested to the patient that pieces of different tissues of the arm be removed for histological examination, but this was refused. It seems that the bones are involved as well as the soft tissue; not so much in the increase in their size, as in the greater opacity of the affected bones, possibly due to an abnormal amount of salts deposited. This difference in the opacity of the bones in the two hands is shown on the *x*-ray picture.

Fig. 3. (*a*) Normal hand; (*b*) Involved hand showing the dislocation and also the greater opacity of the bones.

In many of the reported cases of partial macrosomia, the hypertrophy is either preceded by phlegmonous conditions with edema, etc., or by edema only due to the paralytic dilatation of the blood-vessels, as in the above case. In the cases where this factor has not been mentioned,

it is possible that it has been overlooked, as no importance was attached to it.

Before endeavoring to point out the connection between the edema and the subsequent hypertrophy in the above case, it is perhaps advisable to state very briefly the prevailing opinion held at present concerning the cause of hypertrophy of tissue.

It is generally conceded that a living cell is capable of developing three physiological activities: functional, nutritive, and formative. Formerly it was supposed that these three activities were the result of a direct stimulation. The functional activity being the result of the weakest, the formative activity the result of the strongest stimulation. This, as has been pointed out by Weigert, cannot be the case, for the functional activity is a translation of the energy stored in the cell body and nucleus, into the specific energy of the cell in question, and attended with a breaking-down of the cell element. The nutritive and formative activities are the diametric opposite of this—a replenishing of the broken-down elements and growth or multiplication of the cell. The former or functional activity has been given the name "Katabiotic process;" the latter, or nutritive and formative activities the "bioplastic process."

In the undeveloped individual, as in the undeveloped cell, the relation of different parts of the whole, to one another, is such that an equilibrium throughout the whole does not exist, or in other words, the tissue tension has not reached the point where it inhibits the bioplastic processes, so that they will continue until this equilibrium is established, after which the bioplastic energy will be forced into a dormant state. Should this tissue tension, either in the individual cell, or in the individual, as a whole, again be disturbed, the bioplastic process will again flare up, and growth will continue until the amount of tissue tension develops, which will again inhibit growth. The equilibrium in the individual cell is disturbed every time a cell is stimulated physiologically, whereby substances are removed from the cell (katabiotic process), but which can be, and are normally replaced readily by the nutritive or bioplastic process, thereby reestablishing the equilibrium. It often occurs that by a pathological irritation more intense than a physiological stimulus, the tissue tension is disturbed to such an extent that not only the nutritive but also the formative activity will be liberated, and we will then have cell division and growth beyond the replacement of normally disturbed tissue or hypertrophy. This growth of tissue is due to the bioplastic process.

There is, however, another way by which the amount of tissue can be increased, and that is by the katabiotic process. If a muscle cell is stimulated it will contract, thereby developing measureable energy and heat; if a gland cell is stimulated, it will secrete a substance characteristic of itself. If a connective tissue cell is stimulated it will deposit an intercellular substance (connective tissue fibers), or, in case of osteoblasts, calcium deposits in bones, the result of the katabiotic process. So it is evident that we can have increase of a certain kind of tissue (connective tissue) as the result of a katabiotic process.

In the above case, is it not probable that the hypertrophy is the result of a disturbance of tissue tension, which in turn was brought about by the edema caused by the paralytic dilatation of the arteries in the tissue involved?

Ribbert has expressed the opinion that tissue tension can be disturbed by a simple hyperemia, the result of which is an hypertrophy of the tissue involved. A pupil of Ribbert, E. Feurst, has taken up this subject, and he succeeded in producing an hyperemia with a subsequent hypertrophy of the tissue involved, by exposing tissues to low and high temperatures. Feurst, however, is of the opinion that it is not the hyperemia alone that causes a disturbance of tissue tension, but that pathological changes in the cells, brought about by exposure to the low or high temperature, is a factor in disturbing tissue tension. In the above case the factor of pathological changes in the tissue due directly to the effect of the low or high temperature, in bringing about a disturbance of tissue tension. can be excluded; instead, we have a paralytic dilatation of the blood vessels with edema caused by a lesion lying remote from the tissue hypertrophied and therefore in no way directly affecting it. This is, therefore, that ideal condition to which Ribbert has referred as being so difficult to produce experimentally, viz., the production of an hyperemia in a tissue, without injuring the tissue directly by the agent which produces the hyperemia.

The present case may also bear upon the theory of special trophic nerves, but it seems to me that there is not sufficient evidence in support of this theory to call for a discussion of it in this connection.

The study of this case is by no means complete, as it is impossible for me to ascertain the nature and extent of the hypertrophy, as histological sections of the tissue could not be made; but it seems probable that we have a tissue hypertrophy, the result of the bioplastic, as well as the katabiotic process.

EXERCISE.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

A certain amount of exercise is essential for the preservation of health. To make a proper use of it, a thorough knowledge of the true principles involved is necessary. Du Bois Reymond, who perhaps offers the most lucid definition of exercise says: "Exercise is the frequent repetition of a more or less complicated action of the body with the cooperation of the mind, or of an action of the mind alone, for the purpose of being able to perform such actions better." It must be clear then that the mere fact of forcing the muscles to perform a definite amount of work is not sufficient for one to secure the benefits to be derived from healthy exercise. On the contrary, the mind and muscular system must act conjointly in order that a good result may be attained. Bodily exercise will only be considered, since the discussion of the complete subject would be foreign to the purpose of this necessarily brief article.

It is difficult to lay down any exact rules regarding the amount of exercise necessary for an individual, since many factors, such as muscular strength, age, season, and temperament, must be considered. Dr. Parkes, who has given much attention to the subject, estimates that every healthy man ought to take daily an amount of exercise equivalent to the raising of one hundred and fifty tons about one foot, or a walk of about nine miles. An equivalent of this amount of work is indulged in by most individuals occupied with the usual trades. The trouble is that in some of them their vocation demands the exercise of certain muscles only; besides, to make matters worse, it is carried on in quarters lacking in the very essentials of proper ventilation, etc.

Ordinary physical exercises as opposed to gymnastic exercises are of the greatest importance both in health and disease. Indeed, it may be questioned whether an outdoor life combined with exercise taken in the pursuit of sport or of games is not, after all, the best mode of regaining and preserving health. There are, however, a very large number of persons who are compelled by occupation to endure a sedentary existence, and for these gymnastics of various kinds afford a useful substitute. The art of breathing correctly is a most essential one and is of more importance than any other means of retaining health. There are numerous series of movements calculated to improve the organs of respiration. The Japanese are greatly given to the practice of these methods and probably there is no race of men living at the present time who possess an average chest capacity equaling that of the Japanese. The necessity, however, of breathing properly is too obvious to need argument. Natural full breathing is an essential to sound health, and in order to increase the capacity of the lungs, there is only one exercise which will effect this purpose and that is to breathe deeply and slowly, until expansion has reached its utmost limit. The methods, of course, employed to attain this object are various and too numerous to discuss within the scope of a short article. It may, however, be stated that to cause involuntary respiration, exercise of speed and strength are required. Perhaps, the best of such exercises is speed running employed with discretion, but swimming, rowing, and walking, especially uphill walking, are all excellent means in the same direction; and it is a fact that the use of the legs tends to develop the chest capacity more effectually than the use of the arms.

It goes without saying that the aged, those whose arteries show symptoms of degeneration, or whose hearts have been weakened by organic changes, and those with lung affections, should undertake no violent exercise whatever, but if they are allowed any outdoor sport at all, should take gentle exercise involving only slow, steady movements. The best treatment in the way of exercise for the young, for the healthy fat persons, for the sound but flabby individuals is often really strong exercise, the form of exercise requiring endurance and speed.

By some authorities sharp walking exercise and horseback riding is recommended in the treatment of suspected phthisis. In the treatment of obesity exercise naturally plays an important part, but in all fat persons the condition of the heart must be considered. Exercise is of the greatest value in the treatment of gout, but rather as a preventive of an attack than as a remedy for the disease. Careful and restricted diet, daily exercise, though not of a violent nature, yet, sufficiently strenuous to open well the pores of the skin, and continued long enough to cause fatigue are the most effectual remedial measures. Exercise and massage in conjunction with abstinence are beneficial even in cases of acute gout.

Many investigations have been made concerning the influence of exercise on the assimilation of food. As regards gastric digestion, there can be no doubt that severe mental and vigorous bodily exertion directly after a meal retards the digestive processes. The entrance of food excites the free flow of gastric juice, which, like all secreting processes, is dependent upon an afflux of blood to the secretory glands. Other parts of the body, notably the brain, thus suffer from a temporary and partial anemia, and hence the great tendency to sleep which so often follows the eating of a hearty meal. At such a time, severe mental work or vigorous bodily exercise must necessarily cause incidentally a corresponding withdrawal of blood from the alimentary system to the brain, or as in the case of physical labor, to the extremities in order to furnish the amount of blood necessary for the proper performance of the functions of these parts. The withdrawal of blood from the digestive organs has the effect of inhibiting gastric digestion, since there has been an interruption to the free flow of gastric juice. Cohn's and Salvioli's experiments on dogs prove the correctness of this theory. The influence of exercise upon intestinal digestion has received attention from other experimenters. Grandeau and Leclerc as a result of their investigations on trotting horses found that this kind of exercise tended to bring about an inhibition of intestinal digestion, this amounting to about 3.4 per cent. of the total organic matter of the food stuffs ingested. Wolff, however, found that increased work will exert the above influence on digestion only under certain peculiar conditions, and that the amount of work and the length of time the work is continued have

but little or no influence on the digestion of food. Some very interesting studies in this line have been made, and as a result it has been found that in spite of the most vigorous exercise, intestinal digestion is not interfered with. A weighed amount of food, of known composition, is at a stated time each day fed to a healthy dog. Analysis of the feces during the periods of rest and of violent exercise shows practically no difference in the amount of nitrogen and fat absorbed. These experiments would seem to indicate that while gastric digestion may be temporarily retarded by vigorous exercise, the ultimate assimilation of food, is practically independent of work or rest. This is further attested by the fact that an ordinary laborer, with only an hour, or in certain factories half an hour for his midday meal, must recommence his work at a time when gastric digestion is just under way, and must continue at his labors when the most important part of digestion—the intestinal digestion—is in progress, and still assimilation of food is apparently as complete as in the case of people of sedentary habits. We are safe then in believing that digestion is favored by rest of the stomach before eating, by gentle exercise of the mind and body after eating, and by undisturbed mental condition.

Men engaged in mental work do not need the same amount of exercise required of those whose occupations involve physical rather than mental effort. Gentle exercise in the open air, such as walking, bicycling, etc., and sufficient sleep and good food, will suffice to keep the functions of the vital organs in good order. Severe muscular exertion can never compensate for expenditure of nervous energy.

It has been proven that the effect of muscular exercise upon the secretion of urine varies according to whether the person is accustomed to exercise or not. The excretion of urea is increased by exercise in the case of those trained to athletic work, while the amount of urea remains unaffected or is even diminished in those instances where moderate muscular exertion is indulged in by those not possessing such training. Thus, it will be seen that an athletic training is productive of a more complete oxidation of the nitrogenous materials of the body, and therefore of a more economic utilization of these substances. In those cases where there is a lack of physical training, sudden muscular exertion is followed by a waste of nitrogenous matter. Good muscular development must not be considered as indispensable to health, nor must strength be regarded as immunity against attacks of disease. It is to be remembered that in many instances trained athletes have developed simultaneously with their general muscular development, a corresponding hypertrophy of the heart muscle, which, while not in itself an alarming condition, may lead to degeneration of the cardiac walls.

Moderate exercise is of great value for hygienic as well as therapeutic reasons, in the treatment of debility, anemia, hysteria, neurasthenia, muscular atrophy, and obesity. In ill-nourished children, as well as convalescents recovering from acute or chronic illness, gentle exercise is of the greatest value in promoting a speedy return to health. Gymnastics can be put to remarkably good use in the treatment of chorea. Physical exercise, in the education of children with inherited neurotic or insane tendencies, has now been introduced in many asylums devoted to the care of such patients, not only as a means of promoting health, but for the purpose as well, of rousing and strengthening the activities of the brain and general nervous system. The aim of general exercise should be to keep the body in good physical condition, not merely to increase muscular development. Gymnastics after the German and Scandinavian methods tend to develop certain muscles at the expense of others. For instance the muscles of the upper part of the body are unduly developed, while the muscles of the thigh and leg are comparatively neglected. Such exercises are of value to attain a definite purpose. They are useful to strengthen certain groups of muscles, to improve deformities, or to correct bad postural habits. But for children, in particular, games are more beneficial than drill and calisthenics. Up to the age of eighteen years it is well not to attempt violent effort in feats of endurance or strength. As a rule, from eighteen to thirty is the period of life when a man can take any form of athletic exercise, not only without injury to health, but with healthgiving effects. Individuals vary, however in this respect, and many men do not mature until they reach the age of twenty-one, and the majority of men may be said to be absolutely at their best for active exercise at about the age of twenty-five. After the age of thirty, except in somewhat exceptional cases, a man is less adapted physically for strenuous activities. Work calling for continued speed is then calculated to place too great a strain upon the heart and blood-vessels. Nevertheless, exercise should be continued in later middle life and old age. The tendency in these days is to take life too easily, and to disregard the need for exercise. This tendency is fostered by the numerous facilities afforded to avoid exertion, such as elevators, and the innumerable opportunities of locomotion found in the streets of modern cities and towns.

There can be but little room for doubt that old people fall into senile decay, often unnecessarily, merely because they do not take a reasonable amount of active exertion. The consequence is that joints stiffen, muscles relax, and arteries harden prematurely, while if old persons were to continue their interest and to participate in those outdoor sports and activities which are possible without overexertion, their lives might be prolonged considerably and the evil day of decrepitude might be longer postponed. With regard to elderly persons who put on flesh more rapidly than is good for the health, and as sweating by baths and drugs and strict diet might be dangerous for such as these, their sole means of salvation from fatty changes and senile degeneration of tissue lies in muscular exercise. It may then be laid down as an irrefutable truth that all sorts and conditions of men require exercise, but exercise taken with discretion and the personal factor in each case duly considered. Women, speaking generally, do not take sufficient exercise. The trend of the present day is for the girls of the richer classes to lead an outdoor and far more healthy life than was formerly the case; but the women of the middle class even now do not obtain either enough fresh air or exercise. The reason that so many women in this and other countries present an anemic and fragile appearance is mainly on account of lack of fresh air and exercise. A woman has need of both these essentials to really sound health as much as has a man.

Wolfe lays down the following axioms as to the regulation of exercise. First, exercise should be

taken out of doors. One of its greatest benefits is that it causes us to inhale full inspirations of fresh air, which thus, amid the millions of air cells in the lungs, coming in proximity with the blood, serves to purify it and send it onward, circulating freshly and purely through the arteries of life. Now, if this air is impure or loaded with dust, or with the effluvia of confined localities, much of the benefit is lost. Second, exercise should not be dependent on the weather; dull, damp air, frosty mornings, and the fear of taking cold, are often the scapegoats of lazy dispositions, of erroneous opinion. The system in a state of activity is less susceptible to sudden changes of temperature than when at rest. Third, exercise should not be taken after long fasting nor immediately after a hearty meal. An hour after an early breakfast or two hours after dinner is the best time for regular exercise. Fourth, do not exercise to extreme weariness. The amount that is beneficial is very different for different persons, and is to be measured by the occurrence of fatigue. With those much debilitated it is often the case that they need to be exercised, rather than to exercise; and this may be done by the use of a flesh brush and by moving or assisting to move the various joints of the body as in active exertion.

N. S. Davis, discussing the treatment of heart disease through exercise and under certain rules that must be observed, praises this treatment highly. However, in taking exercise the muscular effort must be slight, although numerous large muscles must be used. Respiration should be deepened but not hurried, and exercise must be graduated, beginning with the lightest. He is of the opinion that all forms of heart disease, accompanied with muscular weakness, with or without dilatation, can be treated with fair hope of success by exercise. The best results are obtained in cases of dilatation which are due to high arterial pressure or physical exertion, and in which there is no, or trifling, degeneration. In the early stage of muscular degeneration the outlook for treatment by this means is favorable. When, however, there is much degeneration or cause for its increase, only temporary improvement can be anticipated. Oertel's treatment is particularly well adapted for the treatment of obesity and fatty infiltration of the heart, although various kinds of graduated gymnastics will also give good results. Of chronic valvular diseases the mitral form most frequently respond favorably to gymnastics, but numerous cases will be met with in which treatment is useless to restore compensation. Improvement of aortic valvular affections is less likely to result.

One of the best modes of exercise to be taken is horseback riding. Hippocrates mentions in high terms of approval the practice of horseback riding at full gallop, as a remedy for certain affections. Oribasius, also passed the highest encomium upon this form of exercise as a remedial measure. The Greeks regarded equestration as a therapeutic means of much value in the treatment of disease. The Romans, as a rule, were not such ardent votaries of horseback riding as the Greeks, nor did they recommend it so widely as beneficial in disease. Bagliva, however, advocated it strongly and is said to have cured two hypochondriacal patients, by causing them to ride in the country on asses. Early English writers usually praise horseback riding. Fuller, in 1740, said that this exercise, upon several accounts, may be esteemed the best and noblest of all exercises for a sick person; whether we consider it with respect to the mind or body. Sydenham was one of the most enthusiastic advocates of horseback exercise as a remedial agent, and declared that it was a sure remedy for consumption. Without going quite as far as the "Father" of English medicine, the fact must be conceded that riding on horseback is a most healthful exercise. The opinion was held in ancient times that horseback riding was under all circumstances harmful to those suffering from hemorrhoids. This view is entertained by many at the present time. Lewis has written recently to show that horseback exercise, judiciously and carefully undertaken, is more often a prevention and cure of hemorrhoids than a cause of them. Many distinguished medical authorities oppose this opinion, while on the other hand, Baron Larrey, Surgeon-in-Chief of the Grand Army, under the first Napoleon, declared positively that the motion of the horse was much better calculated to cure hemorrhoids than to cause them. Lewis states that he himself had witnessed the good effects of horseback exercise in the affection. Some of the patients had the disease in the form of varices in the anal region; while in others it was attended by regular organized tumors. The pressure of the saddle and the motion of the horse in these cases appeared to exert a most salutary influence in removing the congestion and the tumors. There can be no doubt that horseback exercise is beneficial in various conditions, and especially in that known as a torpid liver. The gentle shaking in riding certainly induces a more active secretion in that organ, and absorption in the intestines, probably by accelerating the circulation.

Medical gymnastics had their origin in Sweden, and are practised largely in that country, Denmark, Norway, Germany, Austria, Holland, and to some extent in France. Neither in the United States nor in Great Britain has the system been received with much favor, chiefly for the reason that the medical profession generally has held aloof, and medical gymnastics are taught and practised by individuals, many of whom are ignorant of the proper manner of applying the methods. In Europe and in Sweden especially, medical gymnasts are thoroughly trained. For example, the requirements for admission as a qualified gymnast, and the courses at the Royal Gymnastic Institute at Stockholm are as follows: The entrance requirements are: Candidates must be of good moral character, and must have matriculated from one of the public colleges. Only persons from good families are admitted, this because the graduates will have to move in the best social circles. The course for men lasts three years and for women two years. The curriculum comprises a complete course in the anatomy of the human body, physiology, theory and practice of medicine, and pedagogical gymnastics. For medical students and physicians there is a one-year course of medical and pedagogical gymnastics. At the University of Uppsala in Sweden, every medical student has to pass an examination in massage and gymnastics. In order to be qualified by the Royal Medical Department as a medical gymnast, it is obligatory to have graduated from the Central Institute. In fact, in Sweden and in some other European countries, medical gymnastics are recognized as a part of medical and surgical practice, and consequently its exponents must be skilful and competent.

Modern gymnastics are divided under two heads, the Swedish, or movement exercises, and the German, or "Turnen" exercises. The Swedish are considered far superior for medical purposes. Peter Henry Ling, a Swede, who was born in 1776, and died in 1839, and who was most instrumental in promoting this form of exercise, divided these gymnastic movements into four main classes: (1) Movements serviceable in the treatment of disease or depravity; (2) movements chiefly useful in promoting and maintaining a normal bodily development; (3) movements suited to rendering recruits in the army and navy strong, dextrous, and enduring and (4) movements for giving outward expression to thoughts or motion. Each movement should have some specific effect upon the inner organs of the body, and for this reason only such motions are employed as have been proven by experience to produce these definite changes. These exercises consist of active movements (voluntary on the part of the patient), passive movements (movements secured by the manipulator) and duplex movements (in which both patient and manipulator take part). Passive and duplex movements characterize in great part the features of Ling's Swedish-movement treatment.

Dr. Zander, also a Swede, has devised some sixty different machines by means of which it is possible to secure accurately regulated exercise for any particular group of muscles in the body. This form of exercise is known as the Zander Mechanico-Medical Gymnastics. While it is highly lauded in some quarters, it has been severely criticised in others, owing to the fact that in many diseases, for instance, those affecting the joints, a trained hand is necessary to supplement the use of the machine. Sargeant of Harvard University has invented a series of developing machines, which are now extensively employed in the United States. The principle involved is the running of adjustable pulley weights between metal rods as guides. Of course in this form of exercising machine only active motions can be employed.

Medical gymnastics deservedly holds a prominent part in the list of the so-called "Natural Methods" in the treatment and prevention of disease. The physician ought to understand something of this method of "mechanico-therapeutics," and avoid such expressions as "out-of-door life," "muscular exercise," and other vague advice when consulted as to the propriety of exercise in an individual case. Each man is a law unto himself, and the kind and amount of exercise beneficial in one case may be entirely unsuited in another. For practical purposes the moderate use of the dumb-bells, Indian clubs, developing machines, bicycling, horseback riding, walking, and similar methods of exercise, will accomplish much in promoting the physiological functions of our organs, and thus assist, in great part, to ward off the ravages of disease.

129 West One Hundred and Third Street.

RHEUMATIC MANIFESTATIONS IN CHILDREN.*

By MONTGOMERY HUNT SICARD, M.D.,

NEW YORK.

INSTRUCTOR IN PHYSICAL DIAGNOSIS, CORNELL UNIVERSITY, MEDICAL DEPARTMENT OF PEDIATRICS; MEMBER OF THE NEW YORK ACADEMY OF MEDICINE.

Acute articular rheumatism in adults is a disease of sudden, severe infection with polyarthritis, and the possibility of endocardial involvement; this, however, does not form an adequate picture of acute articular rheumatism in children. One sees in them such manifestations as endocarditis, chorea, tonsillitis, the various erythemas and subcutaneous nodules, overshadowing the arthritic symptoms, which apparently play but a minor part. Any one of the above conditions may be associated with disease of the endocardium or pericardium, and in some cases these last are the sole evidences of the rheumatic infection; so that to consider the joint symptoms alone as an indication of the severity of the case would prove a dangerous error.

The arthralgias seldom present the evidence of inflammation seen in the adult, redness, swelling, extreme pain, and tenderness; but there is moderate pain on motion, so that the patient chooses certain positions of the limbs for comfort. On examination we find tenderness in the periarticular structures, over the insertion of tendons and over ligaments. The inflammation selects by preference the articulations of the lower extremities, the knees, ankles, or the small joints of the foot; if the upper extremities be affected, the elbows, shoulders or wrist, or the small joints of the hands suffer. Infrequently the vertebral joints are affected, chiefly in the cervical region, where they may be accompanied by torticollis.

These attacks last a few days or weeks, and then subside, but unfortunately they show a tendency to recur, and a rheumatism of benign appearance may last with exacerbations for weeks or months, sometimes causing considerable deformity of the parts.

Rheumatism is of very uncommon occurrence in children under 2 years of age, and of very rare occurrence in those under 1 year of age. When localized swelling, pain, and tenderness are present in an infant, they almost invariably prove to be scurvy, and quickly clear up on the proper change of diet. Rauchfuss found only five cases of rheumatism in 15,000 nursing infants, and Wiederhofer found but one among 70,000. Miller was able to collect from the literature only 19 authentic cases. After the second year, however, the disease becomes more common, and attains its greatest frequency after the tenth year.

Quoting from Grancher and Combe's "Traité des Maladies de l'Enfance," we find that rheumatism of childhood is distinguished from that of adult life:

"(1) By the character of the arthropathies, which, are far from having the importance and the aspect which they have in adults; (2) by the frequency of abarticular rheumatism; (3) by the frequency and gravity of cardiac complications."

The nursing infant cries, is restless, does not take the breast, has fever, favors one extremity and screams with pain when moved. In most children of 2 years and over, the onset is not sudden, the temperature is comparatively low, usually not above 102°, there is moderate pain and malaise; examination reveals a slight puffiness or moderate swelling. The joints most often affected are the knee, the ankle, the elbow or wrist, or the small joints of the foot or hand; sometimes the symptoms are limited to one joint alone, sometimes they are multiple. In some cases there are fever, restlessness, and pain of an indefinite character, but without true rheumatic swelling. Some cases have no fever, and the pain is so slight that it does not make much impression upon the mother: these children are not even kept in bed and are able to walk about. These mild subacute attacks are not infrequently overlooked when occurring in the upper extremity, for it is often the limp which attracts one's attention to the stiff or painful joint,

*Read before the Monthly Medical Club of New York, December 8, 1905.

and if this is not evident by observation, the disease may escape detection.

A child may have afternoon temperature, which subsides after the night's rest, and which recurs again on the following days; influenza, malaria, indigestion and typhoid fever are all diagnosed, when minute examination would perhaps reveal a sensitive joint, tendon, or muscle; if not, the occurrence of endocarditis, of chorea, or of a persistent anemia would tell us the nature of the trouble. Tenderness often affects the ligaments, tendons, and muscles rather than the joint; muscular spasm is sometimes marked, and when persisting, makes one think of beginning tuberculous disease.

Only a few days ago I saw a child of 3 years who had been under observation for some time with a harsh, whistling, mitral murmur and evidence of cardiac hypertrophy, and with no history whatever of previous rheumatism. Upon the occasion in question she had a temperature of 103°, with no cause that could be ascertained by the mother, and no complaint on the part of the child. Careful examination revealed the presence of slight tenderness in the calves of the legs. This child was having a recurrent rheumatic attack, abarticular in character; without the endocarditis to give us a clew in this case, the rheumatic infection might easily have been overlooked.

Endocarditis is remarkable not only for the number of cases in which it occurs, but also for the extent of the inflammatory changes; it exists in a very large percentage of cases, exceeding considerably the same complication in adults. The most frequent lesion is insufficiency of the mitral valve; the aortic orifice seems to escape the ravages of disease to a greater extent in children than in adults. The endocarditis may exist alone or coincidently with pericarditis, or with other manifestations of rheumatism; it occurs most often early, contemporarily with the first articular symptoms, but may wait for a recurrent attack; sometimes it precedes the joint infection. A striking feature of endocarditis in older children is the number of cases one sees, in which no history of a definite rheumatic attack can be obtained; it may even require the closest questioning of the mother to bring out the history of pains, however indefinite, usually called by the parents growing pains, and considered to be of no importance; in some cases the pain has escaped notice altogether, but the endocarditis bears evidence to the presence of the infection. If these patients of indefinite history be kept under observation, articular symptoms are almost sure to arise at some future period.

True ulcerative endocarditis in little children is extremely rare. S. S. Adams, of Washington, D. C., has collected all cases reported in children under 15 years of age, 46 in number; three were congenital, and three only acquired under one year, the others were all above three years of age.

Pericarditis is more important from a prognostic standpoint, but fortunately is of less frequent occurrence than disease of the endocardium; occurring in about 18 per cent. of rheumatic cases, it may be taken as the transition stage between benign and severe cases of acute articular rheumatism. It forms a danger to life in the acute stage, during convalescence, and during the months which follow. The dry form is not always diagnosticated, and Koplick thinks it occurs oftener than we imagine. If general it is apt to be accompanied by fluid, which, when absorbed, may be followed by adhesions; so much thickening may result that the pericardial sac is obliterated, but fortunately this is unusual. In some cases of pericardial effusion I have seen, bronchial voice and breathing have been present over the upper left chest, due to compression of the lung, by the distended pericardial sac. Signs of the enlarged sac may also be made out in the back.

Endopericarditis, then, adds much to the gravity of the situation; Cadet de Gassicourt found that out of 100 rheumatic children, 29 were compensated, while six died suddenly, these latter being pericardial cases. Some children are touched only lightly by the inflammation, but the majority have incurable heart disease, which causes death during adolescence, or which hampers the patient throughout life.

Pleurisy manifests itself as an effusion; it may be double (though usually not), and, like endocarditis, occurs either during the course or decline of the rheumatic attack, usually the former. Cadet de Gassicourt has seen the pleurisy precede the arthropathies. The effusion is apt to coexist with endocarditis; it may be absorbed without leaving traces, and if not infected does not suppurate. These pleurisies may be difficult to separate from the pleurisies of tuberculous origin, and we may have to rely upon cyto-diagnosis for a solution. However, it must be said that inflammations of the serous membranes, the pleura, peritoneum, and pia mater were formerly much more frequently ascribed to rheumatism than they are at present.

Attacks of pulmonary congestion accompany the cases of endopericarditis; they are manifested by dyspnea, cyanosis of pallor, rapid pulse, and many fine moist râles; they may go on to pulmonary edema and death.

Not infrequently *chorea* is a precursor of rheumatism; or the first sequel which appears after the chorea may be endocarditis. It may also occur coincidently with rheumatism or endocarditis, or with both. The three conditions are so closely associated that when finding one it is well to suspect the presence or the advent of the other two. When acute articular rheumatism occurs in a choreic child, the nervous symptoms may subside for a time, to recur at the subsidence of the rheumatic attack. Although many writers differ as to the rheumatic element of chorea, Holt finds over 56 per cent. give evidence of rheumatism, and thinks that there is a large group of cases which may be classed as rheumatic chorea. Crandall gives the following interesting statistics from 111 cases of chorea: Previous arthritic symptoms were present in 37 per cent., concurrent arthritic symptoms in 24 per cent., and subsequent arthritic symptoms in 15 per cent. of the cases.

A curious lesion which is not infrequently seen in children is the occurrence of *subcutaneous nodules;* these nodules were first described by Barlow and Warner among the English writers; and by Jaccourd and Meynel among the French; they consist of little tumors situated beneath the skin, free from it and attached by a pedicle to the tendon sheaths, ligaments, or to the periosteum; they are usually found around the elbow joint, connected with the condyles of the humerus, the olecranon, and with the tendon sheaths of the forearm and hand; with the clavicle, the sternomastoid muscle and the skull, with the patella, the spines of the vertebræ, or the crest of the ilium; they are usually about the size of a pea, though they may be larger, and may occur in crops, as many as 50 having been counted at one time. They are composed of fibrous tissue and may undergo degeneration and disappear in a few weeks, or may remain for months.

They appear coincidently with the rheumatic attack, or may be free from it, and are not as commonly seen in this country as abroad. Barlow and Warner found them to be almost always associated with heart disease, and, moreover, with heart disease of a progressive character. Goodhart found them in as many as 23 of 50 consecutive cases of rheumatism admitted to the Hospital for Sick Children, London.

The *erythemas,* nodosum, marginatum, and circinatum may occur in childhood, and of these manifestations erythema nodosum is the most common. The nodes are situated mostly along the tibial regions and the extensor surfaces of the forearm; they are the size of a pecan nut, have their long axes parallel to that of the limb, are red, raised, inflamed, and exquisitely tender; upon fading they leave ecchymotic spots. I have seen them independent of any articular attack, although they are always suggestive of rheumatism.

Tonsillitis and *pharyngitis* are thought to be rheumatic; certainly sore throats yield to rheumatic treatment, and many cases of typical articular rheumatism are ushered in by such an attack. I have in mind a boy, who, with a mild tonsillitis, for which he was kept in bed solely as a precautionary measure, shortly afterward developed slight swelling and pain in the wrist joints, followed in 24 hours by acute cardiac dilatation; recovering sufficiently to gain a slight degree of compensation, he developed a septic endocarditis of typical course, with pericardial effusion, pulmonary and cerebral hemorrhages, which soon led to his death. Of course such cases are not always rheumatic in origin, but the tonsil forms as good a portal of entrance for the organism causing rheumatism as for that of sepsis.

Torticollis may be of like origin and is sometimes associated with sore throat. Not long ago I saw a little girl with torticollis of two days' standing, with pain and tenderness over the sternomastoid muscle which soon gave way to the use of salicylates. Tonsillitis and cervical adenitis may be present as well. When the torticollis is due to vertebral arthritis, we must be careful not to confuse it with torticollis due to cervical Pott's disease, which is generally of longer standing and more gradual onset.

Anemia is present during the attack as well as after it; it is severe and often acute in its onset, and delays convalescence; if persistent it predisposes to another attack. Goodhart goes so far as to say that in every anemia without cause, he closely questions the parents regarding rheumatism in themselves, in order to establish a rheumatic tendency in the offspring.

Purpura is seen as a complication, though not as often as in adults.

Differential Diagnosis.—There are conditions which may be confounded with rheumatism at the different periods of life. In infancy there are—scurvy, acute osteomyelitis, gonorrheal arthritis, syphilitic epiphysitis, hereditary syphilitic bone disease, and hemophilia. In older children there are osteomyelitis and tuberculosis.

In scurvy the children have been fed upon proprietary foods; about the joint, usually knee or ankle, there is a spindle-shaped swelling of extreme tenderness, and frequently accompanied by discoloration; the swelling may extend also over the shaft of the bone; ecchymoses occur and there is bleeding and discoloration of the gums. The symptoms soon clear up on the addition of fresh milk, orange juice, and beef juice to the diet.

Acute epiphysitis, acute purulent synovitis or acute osteomyelitis is a form of pyemia, and is suppurative from the outset, beginning in the epiphysis and soon invading the joint; there are a chill, rise of temperature frequently high and septic in course, prostration, restlessness, and stupor. There is diffuse swelling with tenderness, redness, edema, and deep fluctuation. The symptoms are too acute for rheumatism, the local signs too well marked, and the child dies in from two to fourteen days. In like manner does gonorrhea take the form of pyemia; it may be manifested primarily by ophthalmia, vulvovaginitis, stomatitis, or inflammation of the umbilical cord, but there are cases on record where no primary lesion, nor any abrasion of skin or mucous membrane could be found.

Acute syphilitic epiphysitis may be present in intrauterine life, and is present to some extent in most syphilitic fetuses, and in syphilitic infants who are still-born; the symptoms usually develop within six or eight weeks of birth and consist of pain, swelling, and tenderness at the epiphyseal line, with pseudoparalysis; separation of the epiphysis occurs with crepitation, and sometimes there is suppuration.

In late hereditary syphilis chronic osteoperiostitis may simulate rheumatism for a time; but the boggy swelling, nocturnal pain, the deformity, and the presence of other syphilitic signs will serve to differentiate the two. Osteomyelitis is confined to the shaft of the bone, and unless the pus burrows beneath the periosteum to the neighborhood of the joints, it is not apt to confuse us. Tuberculous joints are difficult to tell in the beginning; the fusiform swelling, pain on pressure over the bones, atrophy of the limb, and the history, will help in our diagnosis. When one joint only is involved, we must bear traumatism in mind. Gonorrheal infection among older children may be monarticular; the inflammation is mostly periarticular, the swelling spindle shaped and exquisitely tender. The disease is obstinate and does not resolve upon rheumatic measures, and may leave adhesions.

To *recapitulate,* we find that rheumatism in nursing infants is very rare; that in childhood the disease is atypical, the joint signs being but little marked; the so-called complications being in children rather types of the disease, for they may occur without joint symptoms, either alone or associated with each other. The whole attack, while seemingly mild and subacute, is capable of causing severe damage to other structures, notably the endocardium, pericardium, and the nervous system. Relapses occur and patients are often left invalids for life.

Alpine Accidents.—Statistics of accidents in the Swiss Alps during 1905 show that 172 climbers were killed and a few more injured. The greatest number of victims was among the Swiss themselves. Of the total accidents, 10 per cent. were unavoidable. The remainder were due to foolhardiness or inexperience.—*The Sun.*

THE FORMATION OF A CUL-DE-SAC FOR AN ARTIFICIAL EYE.*

BY FRANCIS VALK, M.D.,

NEW YORK.

This case is presented to the section for two reasons. We have the very unusual traumatism to the orbital contents, and the necessity for the operation of forming a cul-de-sac by transplantation of tissue. Mrs. —— was referred to me by Dr. Gates, and I have been fortunate in having her consent to be present to-night, as this case is a private one, the operation having been performed at Kingston, N. Y., November 23, 1905, nearly two months ago. The accident occurred at Kingston on July 22, 1902, and is unique in its history. It is rather difficult to understand how this severe traumatism should have happened. She was at an exhibition of fireworks at a park, looking upward, when one of the sticks from a rocket, that had been fired, in falling, with the burnt end downward, passed through the brim of her hat, lacerated the eyeball, tore out the lower part of the conjunctiva and the free border of the lower lid, passed down through the cheek and out below. It was pulled out by one of those present, and the lower outer edge of the orbit was found to have been broken. The traumatism seems to have torn out the eyeball, or part of it, and probably part of the muscular cone, as I have not noticed any movement of the tissues of the orbit by muscular action.

It also seems to have fractured the outer part of the orbital plate of the superior maxillary bone near the articulation of the malar, but did not injure the infra-orbital nerve. There has been some loss of the bone of the edge of the orbit from the depression at that point. After the accident she was taken home and under ether the wound was cleaned, the remains of the eyeball and the loose portions of bone removed. The wound healed kindly and left the patient in the condition shown in the photograph.

The burnt end of the stick must have penetrated the cheek first, as there seems to be some discoloration of the tissues at the point of the fracture, probably from a deposit of carbon. On the first examination of Mrs. —— I found the superior lid and cul-de-sac intact and perfectly normal in every way, the superior portion of the ocular conjunctiva presented smoothly over the contents of the orbit to the exact horizontal meridian, where it was joined by the straight edge of the lower lid without any evidence of the Meibomian glands or cilia. The free border of the lid had evidently been torn away. The disfigurement caused by the accident was so great that the patient seldom went out and then had to wear a cover over the orbit to hide this condition. On November 23, 1905, assisted by Dr. Gates I operated on this patient at her house for the purpose of forming a lower cul-de-sac so that she could wear an artificial eye. In attempting this procedure I determined to follow out the method of Weeks in every detail with a Wolf's graft obtained from the inner aspect of the arm. It is very evident that in this operation perfect asepsis is necessary, that the technique of the operation must be carried out very rapidly, that at no time must the graft be allowed to cool but must be kept constantly moistened in warm normal salt solution and that the graft shall be quickly and securely attached to the periosteum of the edge of the orbit. This is a brief outline of the procedure necessary, in my opinion, to secure a reasonable success. Weeks has published the entire method of operating and it is not essential to repeat it here* except so far as I have detailed above what seem to me the most necessary points to be carefully observed.

This is the second time I have attempted to perform this operation, and I attribute the success in this case to the fact that I followed out all the suggestions in every particular. The result in my first operation was fairly good but not as successful as in this case, as I then tried to change the procedure somewhat, using a glass eye in place of the rubber plate. Every step was according to Weeks' suggestion, and I think the result shows the necessity of careful, rapid work along the proper lines. I think that the suggestion of attaching the graft to the periosteum of the edge of the orbit is probably the keynote to the success of the procedure, as it must render the graft much more immobile and in that way assist in its attachment to the tissues beneath, while the rubber plate readily retains the normal temperature of the body better than that of an artificial eye.

As to the complete final result in this case I do not know what it will be. Two months is probably too short a time for positive prognosis of the future and "time alone will tell;" but I have done other work with the Wolf's graft and while I have had a certain degree of shrinking it has not impaired the final success of the operations.

The other photograph gives an excellent picture of the present appearance of the patient with the artificial eye in position. On removal of this artificial eye the graft appears to be firmly attached to the tissues beneath, forming a complete cul-de-sac for the prosthesis. As it is now more than four months since the operation, I do not think we will have any further shrinking of the graft, as changes of that nature generally take place before the end of the second month; so that at the present time we may consider it a success. In conclusion it seems to me that no special plastic operation can be adapted to all cases. Some will do well by the implantation of the Thiersch graft, particularly so in the cases where we have a loss of the conjunctiva of the upper lid. The Maxwell operation, as reported by Ball, seems to meet the requirements of those cases, in which the lower cul-de-sac is so contracted that an artificial eye will not remain in place. My case is reported for the reason that, after a careful consideration of other methods, the procedure of Weeks seems to promise the best final result, and the ultimate story, up to the present time, seems to justify that conclusion.

STRANGULATION OF SMALL INTESTINE THROUGH A SLIT IN THE OMENTUM.*

By CHARLES GOODMAN, M.D.,

NEW YORK

ADJUNCT ATTENDING SURGEON TO BETH ISRAEL HOSPITAL AND MONTEFIORE HOME; CHIEF OF SURGICAL DEPARTMENT, MOUNT SINAI HOSPITAL DISPENSARY.

The importance and great value of the omentum in guarding the visceral contents of the peritoneal cavity, and the readiness with which it responds to an impending bacterial invasion by walling off the offending organ from the general cavity, is well known to every abdominal surgeon. The hernial orifice, whether diaphragmatic or inguinal, is almost invariably guarded by the omentum in its effort to protect the intestine from possible impending injury. The case herewith reported demonstrates the omentum defeated in its effort so that it became itself a menace, and which but for the timely surgical intervention would have caused a fatal obstruction of the bowel.

Patient, J. S., age 63 years, Russian, was admitted to Beth Israel Hospital December 17, 1905. Family history negative. He had been an inveterate smoker for many years and had been in the habit of taking a glass of whiskey before each meal. He had long been troubled with constipation and as long as he could remember he has had a cough, with attacks, at times, of difficulty in breathing. Two years before admission to the hospital he was run over and received several bruises about his extremities, but he was not confined to bed. Some weeks after this accident he noticed the hernial swelling in the right groin.

Three days before admission, after his evening meal, he was suddenly seized with acute colicky pains in the abdomen. Earlier in the day he had taken his usual laxative, but without result. Ascribing his pain to an attack of indigestion, he brought on emesis and then took two compound cathartic pills. The pain continued throughout the night, and towards morning he had vomited several times. He then sent for a physician. He was treated for two days more, but his condition became worse. He was therefore sent to the hospital, and upon admission presented the following condition: Temperature, 101.°; respiration, 28; pulse, 100 and small. Tongue coated and dry, vomiting continuous and of brown fluid consistency. The abdomen was very much distended and tympanites was present.

There was a right bubonocele, easily reducible, the inguinal ring admitting two fingers. Urine showed a trace of albumen with hyalogranular casts. Laparotomy was immediately performed under ether anesthesia. As soon as the peritoneal cavity was entered several coils of distended, very much congested, and lymph-covered small intestine forced their way through the wound.

Exploration of the peritoneal cavity with the gloved hand revealed a mass of collapsed small intestine and attached omentum in the right iliac region. The mass being movable, it was readily delivered for examination through the wound. This mass when spread upon the abdomen revealed a coil of small intestine about eight inches in length, which had passed through an opening in the omental apron, about one inch from its free border. This coil of intestine was twisted on itself and strangulated, forming a volvulus, and was so firmly wedged in the slit in the omentum that it seemed impossible to reduce it without injury. The strangulation was released by dividing the omentum from the free border through to the constricting slit.

The intestine, upon being released and untwisted, readily resumed a viable appearance, and the collapsed portion began to distend. As it was evident that the obstruction was relieved, the abdomen was closed by layer sutures of catgut reinforced by a few of kangaroo tendon for the rectus muscle.

The stomach was then washed with a weak solution of bicarbonate of soda and the patient returned to his bed. The vomiting ceased immediately after the operation, and eight hours later the patient had a spontaneous fluid movement and his condition improved decidedly. The patient was discharged four weeks after admission to the hospital, and soon returned to his former employment.

The literature on this unique condition is rather scant. There are, however, a number of cases of intestinal obstruction reported which were caused by a slit in the mesentery. Treves, in his monograph on "Intestinal Obstruction," has an illustration of a similar case to the one here reported, the specimen of which is on exhibition in the University College Museum.

In 1889 Dr. Brown reported a case in the *Medical Standard*, of Chicago, in which the postmortem made on a patient admitted in a moribund condition to the hospital revealed a slit in the omentum through which several coils of intestine had passed which had become strangulated and produced a fatal obstruction. According to Treves, these slits in the omentum are either congenital or traumatic in origin.

The history and findings in this case would point to a possible adhesion of the omentum in the region of the right inguinal hernia, which, if we can accept the history as given by the patient, was caused by accident; the constant pressure of the intestine against the adherent apron had caused a stretching and an attenuation of this structure, which eventually gave way and permitted the coil of intestine to pass through and become strangulated.

FOREIGN BODY IN THE ORBIT.

By T. A. BOOT, M.D.,

HOLLAND, MICH.

On the evening of December 22, 1905, Mr. D——, aged 68, of drinking habits and being at the time very drunk, had a fall, as a result of which the left eye was severely injured. There was, I am told, considerable hemorrhage, but aside from spending three days in bed he had no treatment.

On February 1, 1906, he came to my office. The contents of the orbit were badly inflamed and swollen; there was free discharge of pus and the eyeball was crowded into the upper inner quadrant. Lifting up and looking under the eyelid I found the cornea clear and vision present.

On February 7, the inflammation and swelling having somewhat subsided, a small black spot was noticed near the outer canthus. To the probe this felt hard, of some size and gave the feeling of dead bone. In the absence of any obtainable history of foreign body this it was supposed to be. As it was firmly imbedded, no effort at removal was made at this time.

On February 10 I removed it with forceps. It proved to be a fragment of clay pipe stem, discolored by age and tobacco, one and five-eighths inches long, and one-quarter inch in its widest diameter, weighing fifty grains. It had been lodged in the orbit forty-nine days.

THE MECHANISM OF THE AORTIC VALVES.

THE precise mechanism of the aortic semilunar valves and their relations to the sinuses of Valsalva and to the openings of the coronary arteries have, until quite recently, been questions of much uncertainty to physiologists. The exact position of these valves during systole was first definitely determined by Hesse and Krehl who, by plunging the fresh human heart into a saturated solution of potassium bichromate, and holding it there in a position of strong systole, succeeded in fixing it in this condition. They obtained specimens in this way which, on dissection, revealed a number of important facts. It was found that the semilunar valves during systole projected obliquely upward in the direction of the blood stream, neither lying flat against the walls of the aorta, as Bücke had believed, nor projecting horizontally inward in the manner described by Ceradini. It was further determined that, during this period of the cardiac cycle a number of strong muscular strands, obliquely placed in the vessel wall about the valves, contracted in such a way that they converted the entrance to the aorta into a narrow slit.

The peculiar position of the valves could be readily explained by the previous work of Ceradini. This investigator had shown that when fluid is forced through a narrow opening into a wide channel, not only is a strong axial current produced, but there are formed, as well, small circular currents or eddies which, moving at the periphery in a direction opposite to that of the central current exert strong pressure upon the upper surfaces of the valves, holding them away from the wall while there is pressure from below, causing their rapid and forcible closure as soon as this pressure ceases. The observations were made by noting the movements of small particles of lycopodium suspended in the fluid employed.

Ernst Mai (*Zeitschrift für klinische Medizin*, Vol. 58, No. 5) has repeated these experiments with improved technique, and, with a rather ingenious apparatus, has studied the action of the circular currents or eddies under conditions of varying pressure and resistance and as influenced by changes in the size of the opening through the valves. His conclusions, apart from their purely physiological interest, may tend to throw some light upon certain clinical conditions. He shows that there is an inverse relation between the size of the opening and the force of the eddies described above. The smaller, therefore, the aperture through the valves (the pressure, of course, remaining the same), the more violent and forcible are these circular currents; the greater, consequently, is the pressure they exert upon the valves from above, and the more rapid and perfect is the closure of these valves. Even very gradual enlargement of the aperture produced very speedy and marked diminution in the force and excursion of these currents.

Reasoning from this point, the function of the oblique muscle-strands of Krehl, which have been mentioned above, becomes clear. These at first sight appear only to throw increased work upon the heart by narrowing the opening through the aortic valves. This they undoubtedly do to a certain degree, but, by narrowing this aperture, they at the same time render the circular eddies more forcible, and thus aid in the rapid and perfect closure of the valves. The importance of this may be better appreciated when it is considered that even the most faultless of the pumps used in the industries, acting without these circular currents, because of the unchanging diameter of the valvular orifice, are operated with a loss of energy, by regurgitation, amounting to as much as 20 per cent.

As Krehl has pointed out, this would account for cases of aortic regurgitation in which the valves themselves remained entirely intact, but in which, by atheroma, the narrowing produced normally by these oblique muscle-bundles, was prevented. Mai further concludes from his experiments that, while the force behind directly influenced the power and efficiency of the circular currents, these were entirely uninfluenced by the resistance offered above the valves. Should this be borne out by further work, it would tend to show that the sharp snapping closure of the valves, so familiar to the physician as an accompaniment of nephritis, is due rather to the cardiac hypertrophy than to the back pressure associated with the high arterial tension.

Mai's experiments cannot, of course, be regarded as conclusive. The necessity for transparency of the walls of his apparatus in order that the currents could be observed, rendered it impossible to include in his considerations the elasticity of the vascular coats. Other imperfections necessarily accompanying mechanical imitation of so delicate an apparatus as the human heart were unavoidable; but, so far as they go, the results of these experiments serve to add materially to our understanding of the aortic mechanism.

THE RADICAL OPERATION FOR CANCER OF THE UTERUS.

THE operative treatment of carcinoma of the uterus has been marked by alternating periods of optimism and pessimism, and at the present time it is scarcely possible to judge, from the literature on the subject, which of these two is prevalent. When vaginal hysterectomy was accepted as the elective operation for this condition, an improvement in the prognosis was looked for. Experience has demonstrated, however, that this assumption was somewhat premature, and in reaching out for a more effective means of eradicating the disease, abdominal hysterectomy, together with the removal of the adjacent tissues and lymphatic organs, was proposed and has been largely employed. While it was soon recognized that this procedure was very difficult and would be accom-

panied by a greater immediate mortality than the simpler and less extensive operations previously in favor, it was expected nevertheless that the ultimate results would justify the employment of the more complex method. J. G. Clark, however, who discusses this subject in the *University of Pennsylvania Medical Bulletin* for January, 1906, believes that the experience of many operators has not warranted the universal adoption of this radical operation. He advocates the removal, as far as possible, of the surrounding tissues without any regard being paid to a possible glandular metastasis, for it has been quite conclusively demonstrated that these patients die from local continuance of the growth rather than from widespread secondary deposits. If the glands are already involved, recurrences are almost unavoidable, even if the most radical measures be adopted.

There is considerable difference of opinion with reference to this question of metastasis in cancer of the uterus, and it has been pointed out by a number of recent observers that the extent of the disease does not furnish any criterion as to the presence or the extent of the metastasis, nor is the size of the gland of any clinical value in deciding whether it is the seat of a malignant deposit. Another peculiarity to which Clark calls attention is the fact that although a lymph gland may be greatly enlarged, it may not necessarily be involved, whereas a neighboring gland of minute size may, on histological examination, be found to contain cancerous deposits. This seems to be a good reason in a way for avoiding the extensive radical operation, especially if it is also true, as claimed by Schauta, that in only 13 per cent. of the cases is the glandular metastasis localized in the pelvic area. Aside from the futility of attempting a complete extirpation of all the pelvic glands, it has also become known that these glands are not the only places in which the cancer cells are deposited, but that the lymph vessels themselves and the surrounding connective tissue are often involved.

With these facts before us the outlook for an improvement in the mortality rate by a resort to a more radical operation for carcinoma uteri is, as pointed out by Clark, decidedly discouraging. Experience has taught that in most cases the radical operation is futile because metastatic distribution is apt to be very irregular; it may be present even in the earliest cases, and when the lower accessible glands are involved the upper inaccessible ones are in most instances also affected. Added to these uncertainties is the largely increased immediate mortality that must necessarily follow this procedure from shock, infection, and other complications. The writer's conclusion, although reluctantly reached, is that we lose more than we gain by the extreme radical operation, and in this he will undoubtedly be supported by many other operators. He still advises the abdominal extirpation of a carcinomatous uterus, and claims that it can be carried out in the most complete and radical manner by the use of the actual cautery. No dissection of the pelvic glands is attempted, with the possible exception of a few which are palpably enlarged and readily accessible. This step is of value, however, only as an aid in determining the general prognosis in any given case. It seems unfortunate that no operative means should have been devised by which more than 50 per cent. of the patients can be saved, but as a matter of fact this is a much hoped for but still unaccomplished desideratum.

Our Brethren in San Francisco.

We hope that the appeal of the joint committee of the New York Academy of Medicine and of the Medical Societies of the Counties of New York and Richmond, printed in another column, will meet with a prompt and liberal response on the part of those to whom it is addressed. It is known that hundreds of our colleagues in San Francisco have lost their homes, their books, and their professional instruments; many have also lost temporarily a great part of their clientèle, for the homes of the latter are destroyed and many are scattered through various nearby towns, and for the time being could not find their doctors even if they remained in the city. The donations made to the Red Cross and other relief associations go to feed the hungry, clothe the naked, and shelter the homeless, and no part of these sums could be diverted to such objects as the replacing of surgical instruments; even if it could, physicians would shrink from accepting it, for it would savor of charity. But no such feeling would or should attach to the acceptance of aid from their medical brethren. We would suggest to those who are inclined to contribute of their means to the needs of their San Francisco colleagues that he gives twice who gives quickly. The need is urgent and the time for aid is now. We would call attention also to the appeal of the Relief Committee of Kings County for contributions of books and instruments. Nearly everyone can spare a few books from his library or a thermometer or a few instruments from his office case, and such will be of exceeding service to the physician despoiled of his armamentarium. But the books should be recent editions, and the instruments should be in good condition and serviceable. Rusty instruments of antique pattern and old books are not worth the transportation, and the committee would probably not forward them, even if they were sent in.

The Investigation of the Street-Cleaning Department.

The investigation of the methods of Dr. Woodbury, Commissioner of Street Cleaning of New York City, instituted by the Board of Aldermen, has been going on in a desultory way for a couple of weeks, with the result thus far which everybody who knew the Commissioner, or knew of him, expected. Nothing whatever has been brought to light which reflects or can be twisted in any way to reflect upon his personal character or the honesty of administration of his department so far as essentials go. No doubt there has been some petty "grafting" by subordinates; the collectors of ashes and garbage are doubtless quickened in their zeal by judicious tips, and may perhaps be neglectful of those householders who scorn bribery even in small sums; but that there has been any wrongdoing or even undue favoritism in the award of contracts or in any other of the large concerns which came directly under the supervision of the Commissioner or his chief lieutenants, no one, we are persuaded, really believed when the investigation was begun. The fault of the Commissioner has been that his attention is fixed too closely on secondary matters—on the economical and scientific disposal of refuse rather than the practical cleaning of the streets. He

would be deserving of praise for the reforms which he has instituted in this direction had it not led to a neglect of his titular duties. He is the Commissioner of Street-cleaning, and that should be his first effort. The refuse collected must, of course be disposed of, but the primary duty of the department is to remove the dirt from the streets, and the manner of its disposal is, albeit important, a secondary consideration. It is better to dump it into the sea, after the old-time wasteful and unscientific methods, than to leave it on the streets, if the appropriations at the Commissioner's disposal will not permit of both collection and disposal. If Woodbury's political enemies had started this investigation along this line they would have had a better chance of "putting him in a hole," but the pit which, in their malevolent shortsightedness, they have tried to dig for him is one into which they themselves are likely to fall.

"The Principles of Ethics."

The Committee on Referendum of the Medical Society of the State of New York has sent to the members of the society a blank form on which they may register their will regarding the adoption or rejection of the emasculated code, or, as it is now called, "principles" of ethics of the American Medical Association. The committee has decided to keep the polls open only ten days after the date of the issuance of the ballot (noon of April 27), so that the matter will be determined at 12 o'clock noon on Monday, May 7. It is therefore too late to discuss the question now, for such of the members of the State Society who have enough interest in the matter to vote at all will probably have done so before this issue of the Medical Record is printed. There may be some, however, who have been dilatory in turning in their ballots. If there are any such we would urge them to mail an emphatic *No* before noon on the coming Monday. If they would ask why they should vote in this way, we would refer them to the analyses of those "principles" presented by Dr. Benedict of Buffalo in the issue of the Medical Record of December 9, 1905, and by Dr. Sturgis of New York City in that of January 27, 1906. "The Principles of Medical Ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public." This is pure nonsense. If the principles are "suggestive and advisory" they are not binding on anybody, whether they are adopted or not, and a vote for approval will mean only that the society commits itself to the commendation of a lot of sappily expressed platitudes without in any way obligating its members to an observance of them. It will make no difference, of course, in the conduct of any member of the State Society whether this inoperative code is adopted or not, for the question is purely academic. If the code were mandatory there would be some sense in it, in spite of its Tupperian phraseology, but with its present weak enacting clause it is even more silly than it is inconclusive, and we hope the great Medical Society of the State of New York, the parent of the American Medical Association, will not make itself ridiculous by adopting it.

Gasoline in the Sewers.

Many delinquencies have already been laid at the doors of automobile users, and probably the list of the undesirable concomitants of progress in this particular field has not yet been exhausted. Public attention has recently been directed toward one abuse connected with the use of gasoline motors in rather dramatic fashion by the series of sewer explosions which has occurred on the West Side in the region between Fiftieth and Fifty-ninth streets, the automobile district. The early suspicions that these heretofore unheard-of accidents were due to the presence in the sewers of gasoline vapor emanating from the many garages in the neighborhood have apparently been justified by the reports of the inspectors of the Departments or Sewers and of Combustibles and of Dr. Ernst J. Lederle, ex-Commissioner of Health, who was commissioned to investigate the matter. The Health Department has accordingly taken the question up and the owners of garages have been notified that if any more gasoline is allowed to escape into the house drains and sewers prompt arrest of the offenders, if detected, will follow. It remains to be seen whether the automobiling fraternity will be more amenable to control in this direction than they have been in regard to speed regulations. The possibilities of a serious catastrophe resulting from the flooding of the sewerage system with this intensely dangerous vapor have been clearly enough portended by the minor explosions that have already occurred, and penalties for the wilful jeopardizing of the lives and property of others in this way could hardly be made too severe.

Primary Carcinoma of the Vermiform Appendix.

The relative frequency of primary carcinoma of the vermiform appendix has become apparent only within comparatively recent years, since systematic histological examination of all appendices removed at operation has become common. A number of careful and elaborate studies of the subject have been made, both in this country and abroad, and the results are summarized in a recent communication by Dr. Leon K. Baldauf (*Albany Medical Annals*, December, 1905), who himself makes a report of three cases from the Bender Laboratory. From an analysis of the cases recorded the conclusion is reached that primary carcinoma is present in from one-third to one per cent. of the appendices removed at operation. The condition is rarely discovered microscopically at autopsy. The growth is most common during early life, occurring usually between the ages of ten and forty, and the largest number being found during the third decade. The disorder occurs with equal frequency in the two sexes. Acute or chronic inflammatory lesions are usually present, and they are responsible for the symptoms demanding operation. The tumor itself while localized gives rise to no pathonomonic symptoms. Direct extension to other organs and metastases are rare. The usual type of neoplasm is the simple alveolar carcinoma, adenocarcinoma occurring next in frequency, while colloid carcinoma is unusual. Conclusive information concerning the relation of primary carcinoma to other diseases of the appendix can be obtained only by careful routine histological examination of all appendices removed at operation.

The Medical and Chirurgical Faculty of Maryland.—At the annual meeting of this society, held in Baltimore Arpil 24-26, the following officers were elected. *President*, Dr. Hiram Woods; *Secretary*, Dr. John Ruhräh; *Treasurer*, Dr. William S. Gardner.

The Fifteenth International Medical Congress.

HELD IN LISBON, APRIL 19-26, 1906.

(Special Cable Report to the MEDICAL RECORD.)

(*Continued from page 673.*)

AT the general session of the Fifteenth International Medical Congress, on April 23, Professor von Hansemann of Berlin delivered an address on the "Significance of Domestication in Relation to Disease in Man and Animals." Professor Crocq of Brussels followed with an address, in which he discussed the "Mechanism of the Reflexes and of Muscular Tone." On Wednesday, April 25, Dr. N. Senn of Chicago addressed the Congress on the subject of cancer, his title being "The International Study of Carcinoma."

The closing session of the Congress was held on Thursday, April 26. At the termination of the meeting the congressists joined in singing the Portuguese national anthem and the president of the Congress, Councillor Costa Alemao, delivered his closing address, in which he expressed the thanks of the members to the Royal House, to the city of Lisbon, to the Government, and to the citizens for the welcome and hospitality they had so warmly extended to all those taking part. He also on his own behalf thanked the members of the Congress for their cooperation in making this one of the most successful of the international congresses that had yet been held. This address was greeted with great applause, and when the speaker had closed Dr. Angel Fernández-Caro, vice-president of the Spanish National Committee, proposed three cheers for President Costa Alemao, which were given in the various tongues of the different nationalities represented. Dr. Miguel Bombarda, secretary of the Congress, then extended the thanks of the assembled delegates to the Royal House and to Portugal for their friendly reception, saying that he was sure the foreign congressists would never forget Portugal and Portuguese hospitality, and would have many pleasant memories of the country and its people to carry back with them to their homes. They had learned to recognize the fact that Portugal's glory did not all lie in its former greatness, but that it was still one of the foremost countries in science and art. The secretary then read resolutions relating to international agreements regarding the regulation of emigration, the prophylaxis of tuberculosis, and the cancer question, which had been formulated as the result of the deliberations of the Congress, and which were adopted. He also announced that the next Congress would be held in 1909, in Budapest, under the presidency of Professor Mueller, and with Professor Grosz as secretary. The Hungarian national hymn was then sung, and Professor Mueller arose amid great applause and in Hungary's name expressed thanks for the honor and privilege of serving as host to so distinguished a body. The president then adjourned the Congress *sine die*.

During the week many delightful entertainments had been provided, which were well attended by the visiting medical men and the ladies of their families. Prominent among these were the dinner given by the King to the official representatives of the various governments, a concert given to the ladies in the Zöological Gardens, and a reception held under the auspices of the Geographical Society. The Government and the municipality also gave elaborate receptions.

News of the Week.

Aid for Medical Sufferers in San Francisco.—The following appeal has been addressed to the members of the medical profession of the Boroughs of Manhattan, Richmond, and the Bronx:

"The undersigned, a committee appointed by the New York Academy of Medicine, the Medical Society of the County of New York and the County of Richmond, appeal to the members of the medical profession of this city for funds to help our medical brethren of California, who have suffered losses in the recent great disaster. The large sums of money already raised by the public must be spent in providing food, shelter, and the necessities of life. It is reported that over five hundred physicians in San Francisco alone have lost their homes and all their medical and surgical equipment. They need direct financial help in order to enable them to take up their work again, and we believe that they will be more willing to accept this help from their medical brethren. We ask, therefore, that every physician send to the treasurer some contribution, large or small, and that it be sent at once. The money will be received and acknowledged by the treasurer, but the list of contributors will not be published. Arrangements will be made to have the fund, when completed, sent to a properly authorized person in California, probably one designated by the California State Medical Society. A final report will be made and sent to each contributor. Checks should be made out and money sent to Dr. Charles H. Richardson, Treasurer, Medical Relief Committee, 336 Lexington avenue, New York City. (Signed) Charles L. Dana, M.D., John H. Huddleston, M.D., Reginald H. Sayre, M.D., for the New York Academy of Medicine: Floyd M. Crandall, M.D., John Van D. Young, M.D., Chas. H. Richardson, M.D., for the Medical Society of the County of New York; George P. Jessup, M.D., Charles E. Pearson, M.D., for the Richmond County Medical Society."

The Physicians' Relief Committee of Kings County has sent out a request for contributions to be sent to the San Francisco County Medical Society. The profession have responded generously, and a first installment of $1,200 was forwarded on May 1. The committee is now sending out an appeal for contributions of instruments, books, etc., for those medical practitioners in San Francisco who have lost their equipment. These contributions will be received and packed by the local Red Cross, and transmitted by the Wells Fargo Express Company, free of charge. The chairman of the Kings County Relief Committee is Dr. L. A. W. Alleman, 64 Montague street.

Seaside Hospital Bill Signed.—The Seaside Hospital and Park bill which authorizes the city to expend $2,500,000 for the purchase of land near the seashore for a public park and convalescent sanatorium was signed by Mayor McClellan on April 27. Several sites have already been inspected, and it is likely that the city will acquire a tract of land at Far Rockaway which includes a beach front of more than four miles and 850 acres of ground. The park, when established, is to be under the control of the Park Department, but will be for the use also of the Departments of Charities and Health, and the Trustees of Bellevue and allied hospitals. Charitable societies may also lease space in the park.

Mosquito Fighting in New Jersey.—Work is to begin immediately on the extermination of mosquitos in New Jersey. Governor Stokes, on April 26, signed the Brown mosquito bill which was passed by the Assembly and Senate some

weeks ago. The measure provides for the appropriation of $350,000, or $50,000 annually for seven years, to be used in fighting the insects.

Patent Medicine Bill.—The State patent medicine bill introduced by Senator Stevens, which provides for the proper labeling of medicinal preparations containing alcohol or narcotic or other potent drugs, and for their inspection, analysis, and regulation of manufacture, passed the Senate on April 27 by a vote of 30 to 15. There was some opposition to the passage of the measure, on the ground that it was in favor of the medical profession and discriminated against druggists.

Pathological Society of Philadelphia.—At the annual conversational meeting held April 26 Dr. Edward R. Baldwin of Saranac Lake delivered an address entitled, "The Mechanism of Resistance to Tuberculosis." The discussion was participated in by Drs. Leonard Pearson, J. J. Kinyoun, M. P. Ravenel, and Joseph McFarland.

State Lunacy Commission.—Dr. William Mabon, the new superintendent of the Manhattan State Hospital, has resigned his position as president of the State Lunacy Commission. Dr. Pilgrim, superintendent of the Hudson River State Hospital at Poughkeepsie, is suggested as his successor.

The Pure Food Bill.—Endorsement in letters to congressmen was given recently by the Chicago Medical Society to secure reform in the national pure food laws. To each of the nine members of the local Congressional delegation was mailed a copy of a petition signed by 550 members of the society. Congressman Mann was especially urged to use his efforts to defeat the two amendments proposed in the House to the pending pure food bill. These relate to a restricted national commission of five experts, and the unrestricted sale of medicines containing narcotics without an analytical label on packages containing them.

American Climatological Association.—The twenty-third annual meeting of this association will be held in Atlantic City at the Marlborough-Blenheim Hotel May 12 and 14, 1906. The secretary is Dr. Guy Hinsdale of Hot Springs, Va., and the members of the committee of arrangements are: Dr. Philip Marvel, 1616 Pacific avenue, Atlantic City, Dr. Jas. B. Walker, 1617 Green street, Philadelphia, and Dr. Thos. Darlington, Fifty-sixth street and Sixth avenue, New York City.

Illinois State Medical Society.—The fifty-sixth annual session of this society is to be held at Springfield, May 15, 16, and 17, under the presidency of Dr. Henry H. Mitchell of Carbondale. The scientific work of the society will be divided into two sections, medical and surgical. The medical section has 44 papers mentioned in the program, and the surgical section 30.

Dr. Albert Vander Veer of Albany has been elected to the State Board of Regents to succeed Mr. Charles S. Francis, resigned.

Health Board in Jersey City.—Dr. John H. Finnerty was appointed by the Mayor a member of the Jersey City Board of Health on April 28 to serve for a period of three years.

Dr. Eugene S. Talbot of Chicago has been unanimously elected an honorary member of the Belgian Society of Stomatology.

Sleeping Sickness in Africa.—A remarkable increase in the morbidity from this disease is reported from tropical Africa. It is stated that it has now reached the west shores of lakes Mweru and Tanganyika, where the natives are dying in large numbers. British Central Africa is threatened, and there is every reason to fear that the disease in time will reach the thickly populated country. It is thought that the spread of the disease is chiefly due to the increased facilities of transport that have accompanied civilization. The natives are now constantly moving, whereas in the old days of tribal wars they did not move far from the native villages.

University Education More Expensive at Bonn.—It is reported from Bonn that owing to the proposed new brewery tax that is to be levied in Germany the restaurant-keepers of that city have decided to increase the price of beer 25 per cent. Bonn is the first university town to take this step, which, it is said, is causing considerable apprehension in academic circles, lest the rise in the price of this pabulum of learning may impel students to prefer some other university town where beer is cheaper.

Plague in India.—India is suffering severely from plague which, during the past month, has increased rapidly in nearly every province. Bengal has been reporting 5,000 deaths a week and Calcutta had forty deaths in one day in March. Bombay has 150 deaths every day. Matters are equally bad in the central provinces, in spite of the efforts to crush the disease by segregation, inoculation, etc.

An Epidemic of Diphtheria.—A serious outbreak of this disease is reported from the town of Barre, Mass., where forty-eight cases have developed. In the Stetson House for Orphan Boys thirty-five of the forty-two inmates are down with the infection.

Adjunct to the Presbyterian Hospital of Chicago.—The directors of the Presbyterian Hospital of Chicago on April 26 announced that $350,000 of the $500,000 desired for the erection of a new private patient building had already been subscribed. It is intended to use the revenue accruing from this part of the institution for the purpose of eliminating the annual deficit which results from the charitable work of the hospital.

International Congress of Chemistry at Rome.—The International Congress of Chemistry was opened at Rome on April 26 by King Victor Emmanuel and Queen Helena in the presence of 1,800 members. The American delegates are H. W. Wiley, Chief of the Bureau of Chemistry of the Department of Agriculture; Prof. Edward Hart, Lafayette College, Doylestown, Pa.; W. D. Horn, Yonkers; C. A. Browne, Louisiana University; C. B. Dudley, Altoona, Pa., and J. U. Lloyd, Cincinnati.

Metric System Bill Defeated.—The House Committee on Coinage, Weights, and Measures on April 27 voted down a motion to report the Littauer bill establishing the metric system of weights and measures.

American Society of Superintendents of Training Schools for Nurses.—The twelfth annual meeting of this association was held on April 26 at the Academy of Medicine. Addresses were delivered by Ex-Mayor Seth Low and Miss A. W. Goodrich, president of the association and directress of nurses in the New York Hospital.

Free Alcohol Bill Shelved.—The free alcohol bill which passed the House a few weeks ago is apparently to be denied consideration before the

Senate through the action of the Senate Committee on Finance on the ground that it will possibly affect the revenue of the country unfavorably.

Meningitis in Virginia.—A severe epidemic of meningitis is reported from Franklin, Va., a town of 2,000 inhabitants twenty miles west of Suffolk, and many deaths have already occurred.

Indiana Cigarette Law.—The Parks anti-cigarette law, passed by the last Legislature, has been declared valid by the Supreme Court. According to the decision, it is illegal to sell cigarettes in Indiana or to keep them for sale, but it is not illegal to smoke them and it is not illegal to bring them into the State.

Alabama State Medical Association.—The following officers were elected at the last meeting of the annual session of this society on April 20 in Birmingham: *President,* Dr. George T. Mc Whorter of Riverton; *Vice-Presidents,* Dr. Louis W. Johnston of Tuskegee, Dr. A. J. Coley of Alexandria City; *State Health Officer,* Dr. W. H. Sanders; *Secretary,* Dr. J. N. Baker of Mobile; *Treasurer,* Dr. Henry G. Perry of Greensboro.

South Carolina Medical Association.—This association, at its meeting held at Columbia on April 19, elected the following officers for the ensuing year: *President,* Dr. T. P. Whaley of Charleston; *Vice-Presidents,* Dr. W. P. Timmerman of Edgefield, Dr. Henry Horlbeck of Columbia, Dr. M. G. Salley of Orangeburg; *Secretary,* Dr. Walter Cheyne of Sumter; *Treasurer,* Dr. C. D. Aimar of Charleston.

Southwest Missouri Medical Association.—At the annual meeting of this association held in Springfield on April 20 officers were elected as follows: *President,* Dr. T. R. Loer, Billings; *First Vice-President,* Dr. Finis L. Anderson, Joplin; *Second Vice-President,* Dr. O. N. Carter, Brookline; *Secretary,* Dr. H. S. Hill, Springfield; *Treasurer,* Dr. W. P. Patterson, Springfield.

South Idaho Medical Association.—At the annual meeting of this association held in Twin Falls, April 20, the following officers for the ensuing year were elected: *President,* Dr. E. W. Klienman of Shoshone; *Vice-President,* Dr. W. F. Pike of Twin Falls; *Secretary,* Dr. J. M. Taylor of Boise.

Plymouth (Mass.) District Medical Society.—Officers were elected as follows at the meeting of this society, held on April 18, at East Bridgewater: *President,* Dr. Frank G. Wheatley; *Vice-President,* Dr. Fred J. Ripley; *Secretary and Treasurer,* Dr. A. C. Smith.

Obituary Notes.—Dr. Israel T. Buckbee of Amsterdam, N. Y., died on April 25, at Fonda, at the age of eighty-six years. He was graduated from the Albany Medical College in 1841 and had been a member of the New York State Medical Society since 1861.

Dr. Chas. F. Moulton of West Roxbury, Mass., died on April 24, of tuberculous meningitis at the age of forty years. Dr. Moulton was born in Camden, Me., and was graduated from Bowdoin College in 1887, and from Dartmouth Medical School in 1890. At the time of his death he was on the staff of the Boston City Hospital and the Massachusetts Eye and Ear Infirmary.

Dr. Benjamin H. Burrell, formerly of Roxbury, Mass., died at Denver, Col., on April 23, at the age of fifty-three years. After practising for some years in Roxbury, he went to Lewiston, Me., in 1882, where he took the Chairs of Anatomy and Physiology in Bates' College. In 1884 he removed to Dorchester, Mass., where he resumed active practice.

Dr. J. P. Waste of Plainview, Minn., died on April 17, at the age of sixty-nine years. Dr. Waste had practised in Plainview since 1865 and was a charter member of the Southern Minnesota Medical Association.

Dr. Emil Hertel of Wilmington, Del., died on April 23, at the age of fifty years, after a long illness. He was born in Germany, but came to this country at the age of fourteen years and received his medical degree from the Jefferson Medical College. He had practised in Wilmington for thirty years.

Dr. Peter L. Horne of St. George, S. C., died on April 21, at the age of sixty-nine years. He was graduated from the Medical College of South Carolina and served through the Civil War as assistant surgeon in the Confederate States Army. He had been vice-president of the State Medical Society, and president of the Dorchester County Medical Association from its organization until his death.

Dr. Emma D. Cook of Detroit died on April 14, at the age of fifty-nine years. She was born in Concord, Mich., and in 1892 was graduated from the medical department of the University of Michigan, since which time she had practised in Detroit.

Dr. J. B. Hinds of New Hope Ala, died at Huntsville on April 21. He was a graduate of the Mobile Medical College, and during the last three or four years had practised in Madison and Jackson counties.

Dr. Benjamin Pennebaker died at Philadelphia on April 25 at the age of fifty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1873. He had been for thirteen years chief resident physician at the House of Correction, and for twenty-four years attending physician at the Franklin Arsenal, and he was also visiting physician to the Holmesburg County Prison.

Dr. Leonard Keehn of St. Louis died at Los Angeles, Cal., on April 9. Dr. Keehn was a graduate of the St. Louis Medical College and had been practising in St. Louis for the past five years.

Dr. J. W. B. Wellcome of Sleepy Eye, Minn., died on April 8, at the age of eighty-one years. Dr. Wellcome was born in Maine and began the practice of medicine in 1850. In 1856 he went to Wisconsin, and in 1858 he located in Garden City, Minn. He removed to Sleepy Eye in 1873, and continued in practice until about a year ago. He served as surgeon in the Tenth Minnesota Infantry during the Indian wars, and later was appointed a pension examiner.

Dr. I. A. Ketron of Clarkesville, Ga., died on April 12, at the age of fifty-eight years. He had practised in Clarkesville since 1883.

Dr. J. K. Milbourne of Clinton, Ia., died on April 12 at the age of fifty-one years. Dr. Milbourne was born in Ohio and was a graduate of the University of Iowa. He had served as president of the Iowa State Medical Society and as president of the Clinton Medical Association.

Dr. G. W. Beggs of Sioux City, Ia., died on April 10, at the age of sixty-nine years. He was born at Plainfield, Ill., and received the degree of M.D. from Rush Medical College in 1862. After his graduation he served for three years as surgeon to the One Hundred and Sixth Regiment Illinois Volunteer Infantry, and at the close of the war settled at Napierville, Ill. In 1885 he was elected surgeon-general of the Union Veteran Army of the United States, with the rank of brigadier-general, and he was for ten years president of the Sioux City College of Medicine.

Correspondence.

THE THIRD ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Special Correspondent.)

THE DYSENTERY BACILLI AND THE SERUM THERAPY OF THIS DISEASE—AMEBIASIS—FIGHTING THE PLAGUE IN JAPAN—BERIBERI—AGGRESSINS AND IMMUNITY.

MANILA, P. I., March 5, 1906.

THE third scientific session of the Third Annual Meeting of the Philippine Islands Medical Association took place in the library of the Bureau of Science, at 3 p. m., March 3.

A paper was read by Professor K. Shiga, of the Institute of Infectious Diseases, of Tokio, entitled, "Ueber die Typen der Dysenteriebacillen und die Serum-Therapie der Dysenterie," and also, "Epidemiologische Beobachtungen über die Dysenterie in Japan." Professor Shiga started his paper by stating that Japan lay between latitudes 21 and 50. He stated that reliable statistics on the bacillary type of the disease went back only thirty years. Amebic dysentery was found in Formosa, but reliable reports had yet been made only on the bacillary form. He stated, for the purpose of his paper, the mainland of Japan need only be considered. During the last thirty years there have been two great epidemics of dysentery, which spread from south to north. The first began in 1883, and lasted until 1888; the second began in 1892 and lasted until 1895, disappearing very suddenly during the latter part of that year. Since that time, smaller epidemics have been encountered, in which as high as sixty thousand people were stricken. Experience had shown that whenever the dysentery made its appearance in the small towns practically everyone in the town was stricken. In larger places as high as 10 per cent. suffered.

The spread is due chiefly to three factors: (1) Healthy persons harboring the bacillus in their intestines. (2) Those persons who only suffered from slight attacks, and consequently, their movements not being interfered with. (3) Those in a convalescent stage of the disease; on account of the organism being found in the stools as long as two weeks after the attack. Research, as made by Dr. Amako, of Kobe, showed that the bacillus could not be cultivated either from the gall bladder or the spleen, and that in all probability the organism is never present in the blood. He stated that among the first to point out the difference between the bacillary and amebic forms of the disease were Professor Flexner and Dr. Strong, at Manila. The speaker said that an important clinical distinction was the fact that the bacillary form is generally very acute, while the amebic form is more or less chronic in character.

In the succeeding years much work has been done by a great many observers, and various types of the bacillus have been found and described. Four different groups have received recognition, but Shiga believed that the classification which he made some years ago should still stand, viz: (1) The type which does not form indol; (2) The type which forms indol with great difficulty; and (3) The type with only slight indol forming properties.

An important observation made last year by Dr. Amako, of Kobe, was to the effect that the bacillus occurs in both an acid and a non-acid form. It was the acid form that was probably described first, from Manila, by Dr. Strong. Owing to the difference in the organisms mentioned above, it could be scarcely hoped that a serum made from any one of them would be effective against dysentery produced by other types. Experiments made showed that horses immunized against type No. 1 and type No. 2, mentioned above, were not immunized against type No. 3. He stated that the best method of obtaining a universal serum that would be effective in any type of the disease was to immunize horses with each individual group of organisms, and then mix the serums from the three different horses with equal proportions, and thus obtain a serum that contained the necessary elements to combat any of the types of the disease that might be encountered. He stated that one of the principal drawbacks to this method, however, was that the dose of the serum would necessarily have to be very much larger than if only the serum of one particular kind of organism was used.

The next paper read was entitled, "Amebiasis, Its Complications and After Effects," by Dr. W. E. Musgrave, Pathologist of the Bureau of Science. He divided his subject into four parts: (1) Diseases accidentally associated with Amebiasis; (2) Diseases of different etiology, in which the association produces modifications in one or both diseases; (3) Direct complications; (4) After effects of amebic diseases.

He said the first heading need only be mentioned, because it would include practically the whole subject of tropical medicine. In passing, he stated that it is important to observe that in beriberi, if the treatment was directed against intestinal parasites it had a most favorable influence upon the prognosis of the coexistant beriberi. Liver abcess was found by Rogers, in India, in 200 cases in making 5,000 autopsies. Strong and Musgrave, in Manila, found liver abscess in 27 out of 400 autopsies, most of which occurred in American soldiers. He stated the most likely route of entrance of ameba to the liver was through bowel lesions, which afterwards became entirely repaired. This belief was strengthened by the fact that abscesses were found in the right lobe in about 90 per cent. of the cases, and that solitary abscesses are practically found only in the right lobe. Liver abscess was very rare in children, particularly those under ten years of age; amebic abscesses in natives of the islands were exceedingly rare, although they had been observed by Drs. McDill and Herzog. Abscesses were also rarely found in Chinese. He stated that ameba are rarely found in the gastrointestinal tract above the ilcocecal valve; that perforating intestinal ulcers were a very frequent complication in untreated cases, but were rare if proper therapy had been instituted early. He stated that in 150 post-mortem examinations made by himself of intestinal amebiasis 6 per cent. showed amebic lesions of the appendix. The nervous system often showed disturbances intimately associated with amebic dysentery, as pointed out by Allen Starr; that old nervous troubles are often "fired up" by dysentery. In conclusion, he stated that in the majority of early treated cases of simple amebic colitis, there were no serious sequelæ, even in cases of long standing, where there had been considerable passage of blood and mucus, and even where there had been sloughs, rejuvenation had been so satisfactory that the perfect function of the bowels was restored. In well-established cases a change of climate was almost absolutely necessary. He stated that the abdominal pain and soreness was a common sequela, and often lasted for years.

The next paper read was that of Professor S. Kitasato, of Tokio, entitled "Ueber die Bekämpfung der Pest in Japan" (Fighting Plague in Japan). He stated that in 1896 an epidemic of plague which was raging in India and Hong Kong at that time, spread to Formosa, and from there Japan was threatened. The strict preventive measures which were instituted were successful in eliminating the spread to Japan proper. The first vessel arriving with plague on board was at Yokohama, in 1896. Since that time vessels have arrived frequently at Nagasaki and Kobe, with cases of plague on board. He stated that the origin of the disease in Japan was not due to persons, but to inanimate objects; that the plague had been introduced into Japan through freight, and in all probability with cotton. At that time it was not recognized that this was a source of danger, and the infection spread rapidly in the principal trading ports. Rats soon became infected, and from them human beings, in all probability, contracted their infection. The principal outbreaks in Japan occurred in 1899-1900 and 1902-1903, both of which times the disease was probably introduced in cotton imported from Hong Kong. The last outbreak occurred in 1905, which was still prevailing, and has probably been one of the worst from which they had suffered.

The total number of cases in Japan, during 1905, was: Tokio, 15; Chiba, 11; Osaka, 134; Nara, 2; Kagawa, 36; Kobe, 90; Moji, 9. He called attention to the enormous amount of money that these outbreaks have cost, citing Kobe, where the first outbreak cost 352,500 yen ($176,250); the second outbreak in Tokio cost 320,000 yen ($160,000), or, briefly stated, 21,333 yen ($10,667) for each victim. During the present outbreak Kobe has already spent 310,000 yen ($155,000), and Osaka, 470,000 yen ($235,000) in combating the disease. He stated that this was only the direct burden, and that the indirect loss, by interference with domestic and foreign affairs, could scarcely be estimated.

The first epidemic could be traced to the importation of raw cotton and Chinese rice from Bombay and Hong Kong, respectively. The second epidemic entered through Yokohama, with freight consisting of raw cotton. The present epidemic at Osaka and Kobe could be traced to a steamer that entered Kobe with raw cotton. The experience of Japan with plague has been that it generally attacks rats first, afterwards man. In February, 1905, many infected rats were found in Kobe, but it was not until May that human victims were detected. He laid particular stress upon the fact that more infected rats are found in the winter epidemics than in summer epidemics.

The manner of combating the disease in Japan consisted first, in the quarantine service, which acted as an outpost defense. On this alone the safety of the country could not be assured. It was necessary to divide the country into small districts, in each of which a Board of Health is necessary to combat the disease whenever it makes its appearance. He praised highly the practice of the United States to have properly qualified medical officers stationed on duty at the principal ports in the world. He stated, by

this means alone, there was greater security to the country than any other measure which has been suggested up to the present time. The most successful method of combating the disease, he had found, was to take measures looking toward the destruction of the rats. If these could be eliminated, the disease could be expected to disappear. He stated that in Tokio alone there were examined bacteriologically from three to four thousand rats daily, and stated further, that the examination of rats was the best guide to prophylaxis, and that Japan had several times been saved an outbreak of the disease by its prompt detection in rats; that isolation, disinfection and quarantine were absolutely necessary, so far as human subjects were concerned. He stated that permanent results could be hoped for only by the construction of warehouses where freight is stored in such a manner as to preclude the entrance or breeding of rats. The present plan in Japan was that whenever a case of plague was found in a house, such house was surrounded by a zinc wall about three feet high, and sunk into the ground about two feet, so as to prevent the possibility of rats burrowing under the guard. Rat-catchers were then sent into this inclosure to destroy all rats, and thereby prevent the infection being spread.

He also spoke of the value of vaccination against plague, citing as an example, that in Formosa, out of 10,176 vaccinated against plague, only seven were attacked, while out of 40,000 who were untreated, more than 500 were infected. For the treatment of those actually stricken with the disease, he stated two methods had been recommended; one, the extirpation of the bubos, and the other, inoculation with plague serum; that the efficicacy of the extirpation and serum treatment depends upon the stage of the disease; that if seen early, favorable results might be expected, but when the disease was more advanced, either method was practically worthless.

Returning to the destruction of rats, he said the question seemed almost hopeless; that in Tokio, 4,800,000 rats had been destroyed, still no decrease in the number was noticeable. He said it had been suggested that *Mus decumanus* was not likely to contract plague, and that it was the bitter enemy of *Mus rattus*, which was very likely to contract plague, and that it was hoped that the decumanus would soon kill off the *rattus*, but such a suggestion seemed to him impracticable, because from actual observation he had noted that the two species interbreed and that the offspring readily contracted plague. He stated that in the winter the rat remained in the ground, but in the summer it lived in the roofs of houses, and this probably accounted for the greater danger of infection in winter than in summer.

In conclusion, he stated that the danger of the introduction of plague in the open ports must increase in the proportion that international commerce progresses; that unfortunately, wherever man fixed his abode the rat usually followed him. The best hope of successfully dealing with plague seemed to him to lie in the calling of an international congress, at which the delegates could pledge substantial monetary support to combat plague in its great epidemic centers, namely, southern China and India; in other words, that a great international army should go forth to fight plague in these countries, and after it was once eliminated there, the disease could be readily eradicated in the remainder of the world, and that plague would then disappear from the face of the earth. He hoped that President Roosevelt, of the United States, would take the initiative in this matter.

The next paper was "Etiology and Pathology of Beriberi," by Dr. Maximilian Herzog, Pathologist of the Bureau of Science. He stated that his paper was not entirely ready for publication, and he would confine himself only to a brief résumé. For that reason no extract of same will be given here.

The last paper read at the congress was that of Dr. R. P. Strong, entitled "A Consideration of Some of Bail's Recent Views in Connection with the Study of Immunity, and a Comparison of the Value of Protective Inoculation with 'Aggressin' with that of Vaccination in Plague." Bail was of the opinion that through the process of bacteriolysis, the non-infective power of an animal might be explained, but he pointed out that the germ-killing properties of the body fluids are primarily worthless for the explanation of the actual process of immunity. In support of this view he called attention to the fact that the rabbit, whose blood serum usually possesses a powerful antagonistic action against the anthrax bacillus, is susceptible to the disease anthrax, while the fowl, whose blood shows the opposite properties, is insusceptible. In short, he stated that bacteriolysis is fallacious in its relation to immunity.

He then took the consideration of aggressins. Krusé first designated these substances lysins, but owing to the fact that this term came to be employed in a different sense, he more recently has proposed the name of aggressins. These aggressins, he believed, are formed by bacteria only in the animal body, and are to be particularly encountered in pathological fluids, such as edemas and exudates, which result from the inoculation of the different microorganisms.

In conclusion, he emphasized that the action of aggressins cannot be explained on the assumption that they are anti-complements or anti-immune bodies, soluble in bacterial fluids, free repositors, etc.; that they must be considered as new substances, which have heretofore been unrecognized, and which are formed by bacteria during infection in the living organism. Dr. Strong stated that the only reasonably sure method of immunizing guinea pigs against plague infection was by inoculation by living attenuated plague bacilli. He stated that he had reported in detail on this method in the second number of the *Philippine Journal of Science*. He stated that the method of vaccination with living organisms was not ideal, because, in order to thoroughly immunize 90 per cent. of the animals, it was necessary to use cultures of such virulence that some of the animals succumbed to the effects of the vaccination itself; that is, to true plague infection. He stated that in his last series of inoculations with aggressins, comprising fifty-three animals, none of the guinea pigs and only 25 per cent. of the monkeys proved on subsequent inoculation with virulent plague bacilli to be immune; so that the results in immunization with this extract of the plague bacillus are not nearly as good as those obtained with the living plague organism which are sufficiently attenuated to be used for human inoculations. Dr. Strong concluded that immunization with the attenuated living plague bacillus must be acknowledged as superior to that of inoculation with extracts, similar to or like aggressins.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HOSPITAL FUND, ANNUAL MEETING—SATURDAY FUND—R. C. P. SIR D. POWELL, PRESIDENT—STREPTOTHRIX INFECTION—PLAGUE IMMUNITY—MEDITERRANEAN FEVER—SPREAD OF CONSUMPTION—THE "RAGGING CASE"—UNIVERSITY OF EDINBURGH—SIR W. CROOKES.

London, April 14, 1906.

The annual meeting of the King's Hospital Fund was held on Saturday, the Duke of Fife, acting president in the absence of the Prince of Wales, presiding. Lord Rothschild, hon. treasurer, reported that the fund received in 1905 the sum of £361,068, of which £237,206 goes to capital. His Lordship thought it satisfactory that the normal receipts might be taken as £123,862, exceeding the expenditure by some £20,000, another satisfactory feature being that the total cost of carrying on the work does not amount to ¾ per cent. on the sum collected. The balance sheet shows a capital sum of nearly a million sterling.

The Duke of Fife in his speech held that the fund has done a great work in the nine years of its existence, having in that time created a greater interest in hospitals, improved their organization, and raised a very large sum of money. But he found one thing which nothing seems to overcome—the apathy of Londoners with regard to their hospitals, the needs and necessities of which have grown enormously in the last twenty years, and if it was not for doubtful finance, sensational appeals, and every form of begging, many would have to close their doors. There must be many, the Duke thought, who could afford to give their guineas but who did nothing, and sooner or later the whole question of maintaining these institutions must be faced. After all, they are not charities in the ordinary sense, but necessities of our civilization. The Duke then read a long letter from the Prince of Wales, passing the whole work in review and displaying the greatest interest in it.

In the General Council's report the subject of contributions to medical schools is referred to, and they see no objection to subscribers to hospitals earmarking their contributions to one fund or another, that being the donor's concern only. The report of the auditor appointed by the Prince to inquire into the uniformity of hospital accounts has been received, and steps are now being taken to bring it before the Sunday and Saturday funds, so that any changes made may meet the views of all concerned. With regard to schemes carried on for profit which offer a commission for the use of the fund's name, the council very properly declines to be exploited and cannot sanction the use of its name for raising money in any form other than direct contributions to the fund itself.

The Hospital Saturday's annual meeting was held on Saturday last. The report, which was adopted, showed an increase in the receipts from workshops and business houses of £1,586, bringing the total to £25,930, the highest in the history of the fund. The expenses amounted to 9.49 per cent. of the receipts. The sum of £500 has been voted toward the establishment of a sanatorium for workers suf-

fering from tuberculosis and for which a site has been secured.

On Monday Sir R. Douglas Powell, Bart., was re-elected president of the Royal College of Physicians for the ensuing year. In the usual annual address he had passed in review the chief collegiate events and referred specially to the course adopted in connection with examinations to be held in tropical medicine, which had received the approval of the Colonial office. The president included brief obituary notices of the Fellows who had died during the year, notes about whom I have sent you at the time of these occurrences. The president announced that he had nominated Dr. W. B. Headley of Melbourne to represent the College at the opening of the public library of Victoria and the fiftieth anniversary of the University of Melbourne. He had also appointed Sir G. H. Philipson to represent the College Royal Sanitary Institute's Congress at Bristol

Streptothrix infection was the subject of a paper by Mr. Foulerton at the Pathological Society, on April 3. Last year he recorded thirty-three cases, and now he adds six others. Of the thirty-nine, one affected the conjunctiva, twenty-one the tissues of the mouth, seven the lung, nine the intestinal tract, five of these last being appendicitis and four right iliac abscess, probably appendical. One case was renal. Out of the thirty-nine patients four were of the unoccupied class, and in seven others the occupation was not ascertained, but of the remaining twenty-eight their occupation was more or less connected with liability to infection from the natural habitat of several species of streptothrix. Stablemen, coachmen, and others connected with grain and grasses, and others whose history suggested herbage as the source of infection, formed a large proportion. Indirect connection of the kind was noticed—thus a cellarman lived in a mews, a woman had spent the summer in the country and had been in the habit of chewing ears of barley and oats, and a young man who had spent some weeks on a farm was one of the lung cases. The presence of the parasite was proved in all the thirty-nine cases. Attempts at obtaining cultures were made in thirty cases, thirteen of these failing completely, four giving a scanty growth in broth only, and thirteen furnishing pure cultures on various media, so that the species could be identified. Two previously described were *Streptothrix luteola* and *S. hominis I;* the former Mr. Foulerton isolated from a case of conjunctivitis and an alveolar abscess; the latter from two pulmonary cases, two abscesses of the jaw, and a tonsil case spreading to the tissues of the neck. This *S. hominis I* is a slow-growing organism, somewhat resembling *Bacillus tuberculosis*, a somewhat similar organism to be distinguished as *S. hominis II;* it grows more freely and differs in pathogenicity for animals. He isolated it from an abscess of the tongue. Two other specis, *S. hominis III* and *IV*, are distinct species of the type met in cattle. *III* was found in the case of renal streptothricosis, *IV* from appendicitis and right iliac abscess.

At the same meeting Captain Douglas, I. M. S., described his experiments as to immunity against *Bacillus pestis*. These completely contradict the conclusion of the German Commission, that the immunizing substance is contained in the sediment only of the plague vaccine and that the clear supernatant fluid is practically inert. Out of three vaccines Captain Douglas found that in two there was more in the filtrate than in the sediment, and in the third the amount was about equal. He showed further that the sediment is made up of many variable constituents, consequently in any attempt to standardize by the weight of the sediment, every precaution would have to be taken to have everything, including media culture, the temperature and sterilization, as parallel as possible. From numerous experiments it appeared that an efficient vaccine could be prepared from cultures so non-virulent that the growth from three Agar tubes failed to kill a rat when inoculated subcutaneously. The dosage will have to be studied by numerous observations on the opsonic power of the blood. One-fifth the dose which has been recommended was taken by two normal men and followed by severe symptoms lasting almost a week in Captain Douglas's own case. The opsonic power rose steadily to its maximum of three times the normal on the 9th day, and rapidly fell again to normal on the 12th day.

Staff Surgeon Reid, R. N., communicated observations on therapeutic inoculations in Mediterranean fever. The dose of the vaccine, he said, could be regulated by the opsonic power of the blood; the temperature was raised in the negative phase which never lasted more than forty-eight hours. In nine cases a fall of temperature was the chief benefit; in four there was also decrease of pain. A gain in weight of about one-half a pound a day was common. One patient gained thirty pounds in a little over a month. The inoculations were also prophylactic and the health of the troops might be greatly improved by its employment for this purpose.

Dr. Wynter Blyth yesterday issued a report on the spread of phthisis, in which he says a health society has been formed in his Borough, Marylebone, to cooperate with the local sanitary authorities in preventing the spread of the disease and diminishing infantile mortality, etc. As to consumption, he remarks that "no age is exempt. The infant at the breast and the octogenarian alike are often infected by the minute parasite; but the special age favoring its development is that of the working period of life, which renders the prevention of the malady so important from every point of view—humanitarian, social, national." He gives an example of seven persons, living in two rooms, one consumptive, and points out the liability of one or more of the others becoming affected. The new society will keep this family under sympathetic supervision.

In the court martial held last week to inquire into the so-called "ragging case" in the Scots' guards, it transpired that the medical officer of the regiment had reported that the officer "ragged" was in a dirty state and had scabies. The commanding officer was greatly shocked at such a "horrible disease" invading his command, and evidently gave a free hand if he did not instigate the cruelty of the subalterns, whose victim, however, desired to give no evidence against his brother officers. The surgeon who made this report about a patient to his commanding officer and left him in such a state of "horror" about a disease he might himself easily contract, owes some explanation to his profession of the course he adopted, especially as his evidence was repudiated by other army surgeons.

Yesterday the University of Edinburgh conferred honorary degrees in several faculties. Professor W. M. Ramsay was made a D.D., the first layman admitted to the roll of honorary graduates in divinity, and this in recognition of the "invaluable services he has rendered to the elucidation of the literature of the New Testament." The LL.D. was conferred on nine persons, including Prof. A. G. Bell, inventor of the first articulating telephone; Prof. Thane, of University College, London, of whom the dean said no one had a more extensive knowledge of anatomical science; Miss Stevenson, a strenuous advocate of the admission of women to university privileges; Dr. E. von Bergmann of Berlin.

Sir Wm. and Lady Crookes kept their golden wedding day on Tuesday and received the congratulations of most of the scientific world.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

A NEW BLOOD TEST—MULTIPLE INJURIES OF THE SKULL AND BRAIN—TUBERCULOUS INFECTION THROUGH THE PLACENTA—A CASE OF MICROGRAPHIA—A CANINE CRETIN.

VIENNA, March 30, 1906.

DR. HOLLANDER HUGO has described a new method of applying the test for the presence of blood with peroxide of hydrogen and guaiac. Hugo states that used according to his method the test surpasses all others in delicacy. If a specimen of urine is to be tested the reaction is carried out as follows: A test tube is one-fourth filled with warm, acidulated urine, then a drop of official tincture of guaiac is added and the precipitate of resin which results is dissolved by the addition of strong alcohol. One or two, or at the most, three, drops of 15 per cent. H_2O_2 solution are then added. If blood is present the usual blue color appears either at once or after several seconds; in order to hasten its appearance the fluid may be gently warmed. In cases in which blood is to be sought for in the urine one should first ascertain whether iodine or bromine is present. The following is a simple reaction for iodine: Ten or fifteen c.c. of urine are mixed with half the volume of concentrated hydrochloric acid, a little chloroform, and a drop or two of 15 per cent. H_2O_2 solution. If iodine salts are present pure iodine is at once set free and gives a cherry-red color to the chloroform. Indican may be tested for in the same way.

A remarkable case of multiple injuries of the skull with extensive destruction of the brain was reported to the Society of Hospital Physicians by Dr. Milko. The patient was a man of sixty-two years, who received several blows with a hatchet on his head three days before entering the hospital. He was treated at home during this time by having his head bound up with rags. The whole skull was found covered with a crust consisting of blood, hair, and dried brain tissue. Bloody brain tissue was oozing from one of the wounds. Two wounds, each about seven cm. long, were present, one on the right side of the frontal bone, and the other over the parietal bone. On cutting through the bridge of skin between the two it was discovered that these bones had been crushed in and broken into splinters for a distance of

fourteen cm. The two plates of bone could be drawn apart and in this way a considerable extent of the cranial cavity could be inspected. It was seen that the cerebral substance for an extent twice as large as the palm of the hand had been demolished and converted into a dirty gray yellow mass. The brain injury extended over nearly all the right frontal lobe, the anterior portion of the right parietal lobe, and even partially involved the corresponding lobes on the left side. The fragmented edges of bone were chiseled off and as much as possible of the damaged brain tissue was removed. After the operation the temperature was 38.5° C. For the first days the patient was stuporous, and then he was restless for several days, but he was never wholly unconscious, and excepting slight paralysis of the facial nerve, no palsies were produced. During the first days there was involuntary defecation and micturition. Under the ordinary methods of wound treatment the injuries healed completely. The case is particularly interesting through the facts that the man recovered from such extensive destruction of the brain and the bone, that no paralysis was noted, and that no infection occurred in spite of the neglect during the first few days after the injury.

Dr. Geza Kiralyfi has reported an interesting instance of placental tuberculous infection which throws light on the question of intrauterine infections in this disease. A woman thirty-two years old, in the seventh month of pregnancy, was brought to the hospital for severe illness. It was found that she was suffering from advanced tuberculosis, and seven days later she aborted. The child was born living, but died an hour after birth, and the mother survived only twenty-four hours, so that both bodies came to the autopsy room together. In the adult body there was found extensive chronic tuberculosis of both lungs, with cheesy bronchial and peribronchial lymph glands. The body of the infant showed no traces of the disease, either externally or in the internal organs. It was therefore decided to attempt to detect the presence of tubercle bacilli by inoculations. These gave positive results, and it was found that tubercle bacilli were present in the liver of the infant. The question of the manner in which such intrauterine infections take place is a difficult one, some observers believing that in these cases the placenta is the portal of entry, whereas others assume a germinal transmission. In the present case it was plainly shown that the tubercle bacilli had traveled from the maternal circulation through the placenta into the body of the fetus. They passed through the umbilical vein into the hepatic vein of the fetus and formed infarcts in the capillaries of the liver, causing the blood of this organ to be infected. The case therefore corroborates the view that tubercle bacilli may enter the fetal body through the placenta, from the mother's blood.

A case of micrographia has been described by Dr. Bleier. The patient was a man of nervous disposition, with a negative family history, who denied syphilis, but admitted excessive alcoholism. He had always suffered from an ungovernable temper, but of late years had become still more morose, quarrelsome, and bad-humored. Noticeable changes had also been observed in the course of the last few years in the patient's gait, speech, and especially in his handwriting. The gait became uncertain and staggering, so that the patient could walk only with very small rapid steps, swaying to and fro, and with the feeling of being pushed forward. This infirmity was especially pronounced in rising from the sitting posture or in standing still, and on several occasions he had fallen down under these conditions, usually on the back. Two years ago he fractured the neck of his right femur as the result of such an accident. The patient's speech was very low, monotonous, and rapid. When irritated these peculiarities became accentuated, although the monotony persisted. The last words of a sentence were repeated several times. The most pronounced change was exhibited in the patient's handwriting, however, on account of which he had been obliged to give up his position of bookkeeper. The handwriting was extremely small; at first the separate letters could be distinguished but toward the end of a sentence they became an illegible scrawl. The rigid attitude and fixed facial expression without any change of countenance were especially remarkable. Arteriosclerosis, Gräfe's symptom, a slight difference in the size of the pupils, which reacted to light, tremor of the fingers, and restriction of vision upward were other symptoms present.

Prof. von Wagner exhibited a dog with cretinism before the Medical Association. The dog came from Steiermark and showed unmistakable evidences of the disease, such as apathy, slow, clumsy movements, thick, short skull and legs, and abnormal development of the soft parts, especially in the face. The examination of the hearing undertaken by Dr. Alexander also gave results characteristic of cretinism. High tones were not perceived by the dog, although he responded with his customary aimless movements to deep and medium tones, indicating a lesion of the internal ear. Wagner expects to obtain interesting information from the autopsy of this dog, and hopes to make use of it in the course of his well-known studies on human cretinism.

MEDICAL SUPERINTENDENTS OF HOSPITALS.

To the Editor of the Medical Record:

Sir:—That was an interesting enumeration of opportunities for recent graduates in medicine that appeared in the Medical Record on Saturday last. But the field was not fully covered; and one omission is all the more striking because the writer of the article in question evidently is alive to the extent to which the practice of medicine, preventive as well as curative, has now become organized in a thousand and one institutions, state supported as well as privately conducted. I refer to his failure to perceive that there is an excellent opening in hospitals for young medical men of executive ability; and yet hospitals all over the country are seeking distractedly for men fitted by taste, talent, and training to become hospital superintendents.

The careers and occupations referred to by your contributor will prove more or less attractive to struggling young medical graduates, according to their needs and temperaments. It is frankly conceded, however, that most of the "opportunities" named are mere rent-payers and pot-boilers; whereas hospital superintendency, or the broader field of administrative medicine, is a field full of promise of honor as well as of profit. Shall I defend the contention that the inspection of hospitals is quite as interesting, fully as profitable, no less dignified, than the visiting of tenements, prisons, slaughterhouses, schools, or dairies? Surely it is not necessary to do so.

Medical men, let me repeat, are needed in hospital administration. Recent graduates can readily find openings in New York, Boston, Philadelphia, Baltimore, etc., as assistant executive officers in the great public and private hospitals. Having supplemented their theoretical knowledge by practical experience, they can step easily into positions as hospital managers. The medical college which first recognizes this situation, and through a chair of hospital economics or administrative medicine starts, each year, a wisely selected few of its graduates on successful hospital careers, will do much to extend its own influence, to promote sympathy between hospitals and medical schools, and to inaugurate an era of scientific hospital control and development.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 26, 1906.

Some Influence in Favor of Better Milk.—Four factors bearing in favor of improvement of the milk supply are, according to R. A. Pearson, laws and ordinances, public demand, milk commissions, and well-conducted dairies. The great drawback is the unwillingness of the majority of people to pay even a small advance for improvement in the quality of their milk. The dairyman is like the manufacturer in that he will not willingly increase the cost of placing his product on the market so long as he can receive no more for it. Dairying on modern conditions requires considerable capital, hard work, and a high grade of intelligence. It is a battle with bacteria, calling for the utmost care at every step.

Jacksonian Epilepsy.—C. K. Mills discusses this condition in a long and exhaustive article, certain salient points of which only can be referred to here. In many instances Jacksonian spasm has been an important or deciding symptom in successfully fixing the site for operation in the case of a cerebral tumor. Several such cases are summarized. The author has had a number of cases of cyst of the motor region, in some of which unilateral convulsions or monopasms have been present, these being evidently due to the unstable condition of the cortex surrounding the cyst. It has been possible to expose the cyst, cut away its roof and so lessen the frequency and severity of the attack. Several clinical histories are given, illustrating the importance of Jacksonian spasm in gross lesions of the cortex, especially in tumor and localized meningitis. In these cases a few features would seem to point with

comparative certainty to gross lesion. In these and in a large number of similar cases, other evidences of gross lesion in addition to the spasm were present. They were chiefly monoplegia or hemiparesis with exaggerated reflexes on the side of the body in which the localized spasm occurred. In unraveling the symptomatology of this general class of cases, the diagnostician must bear in mind (1) that tumors situated in other parts of the brain than the motor cortex may cause Jacksonian epilepsy; (2) that other lesions besides tumors situated in the motor cortex may cause this form of spasm; (3) that it may occur in toxic and other disease in which no demonstrable focal lesions are present; (4) that a spasm closely counterparting the Jacksonian type may be observed as a reflex or a hysterical disorder; and (5) that Jacksonian epilepsy may be simply an integral part of the entire expression of a case of idiopathic epilepsy. In some instances Jacksonian epilepsy apparently of the usual motor area type is observed in tumors of the cerebello-pontile angle or of the cerebellum. The gross lesions of the motor area which cause monopasm or hemispasm counterparting that produced by tumors are depressed fracture, localized meningitis, meningeal or cortical hemorrhage, local hemorrhagic encephalitis or cortical polioencephalitis and focal necrosis or embolism including cases associated with generalized arteriosclerosis.

New York Medical Journal, April 21, 1906.

The Bile Acids as a Remedy.—A. C. Croftan declares that the bile acids may be properly employed in (1) intestinal putrefaction, (2) hepatic insufficiency, and (3) gallstone disease. In (1) they check the development of putrefactive intestinal parasites by direct contact and are powerful cholagogues, hastening peristalsis, aiding in the emulsifying of the fats, promoting their absorption, and preventing the formation of poisonous acid by-products. In (2) the stagnation of the bile is prevented, pressure on the hepatic cells through the biliary channels is removed, and the cells perform their functions more freely. In (3), while the bile acids cannot dissolve a calculus already formed, they may aid in preventing further formation. Of the two acids glycocholic is the cheaper and should be administered in the form of the sodium salt. The author has been in the habit of giving half-grain doses at frequent intervals until the proper effect is produced. Aside from chemical results we have three chemical evidences that enough is being given: (1) the disappearance of sulphides from the stools, (2) the disappearance from, or great reduction of, indican in the urine, and (3) the appearance of the bile acids in the urine. Some simple chemical tests easily applicable by any physician are given for the determination of the three points just enumerated.

Brow Ague: Frontal Sinus Congestion with Periodical Headache.—Three clinical histories are summarized by F. Woodbury. In all, the pain was increased if the patient bent forward as in picking anything up from the floor, and on introducing the nasal speculum congestion and swelling of the middle turbinal mucosa were noted. Presumably, says the author, the same condition extended into the accessory sinuses, and probably blocked the outlet from the frontal cavities and ethmoid cells. Tapping with the finger end over the superciliary ridge, on each side, increased the painful sensations. There was no external swelling or redness; and apparently no active catarrhal condition. The general condition was first class in all the cases, with no evidences of any cachexia or toxemia. The author believes that in this class of cases some vasomotor factor is the fundamental disturbance. The nasal mucosa alteration may be due to malaria or to influenza. He gave speedy relief to his patient by applying cocaine and adrenalin followed by injections of moist hot air and alkaline fluids into the superior meatus. A saline cathartic was ordered, followed by small doses of quinine, camphor monobromate, and acetanilid. Small hypodermics of morphine were given when the case seemed complicated with neuralgia. Later the usual nerve tonics were employed.

The Association of Adenoids and Deafness in Young Children.—P. D. Kerrison believes that many cases of chronic catarrhal otitis media in adults have their origin in diseased conditions incident to child life and that chronic deafness, even in young children, is far more common than is generally supposed. In the examination of the latter class of patients we generally find retraction of the drum membrane, which may be considerably congested. If this condition is bilateral we can predicate nasopharyngeal obstruction. The congestion is not confined to the periphery and region of the handle of the malleus as in adults with tubotympanic congestion, but is more extensive, generally affecting the greater part of the membrana tensa. The author gives the detailed findings in fifty children. This class of patients is frequently neglected and they do not come under the otologist's care until a chronic lesion is present. The nasopharyngeal obstruction should be promptly removed, and a month later the hearing should be again tested. If the membrane is still retracted or congested, inflation by the Politzer method or by catheter, if the age and temperament of the patient will permit, often aids in establishing the results for which the operation was undertaken. Patent Eustachian tubes, improved hearing, and restoration of the drum membranes to a more nearly normal condition should be regarded as among the tests of a successful result.

Journal of the American Medical Association, April 28, 1906.

The Parasitism of the Tubercle Bacillus.—Theobald Smith finds from his studies on cattle that there are three main portals of entry of the tubercle bacillus into the system, the upper air passages, the lungs, and the small intestines. Infection by other routes, such as the skin, is very exceptional. The lodgment in the lymph nodes is accomplished without any apparent lesion whatever, and the nodes act as temporary barriers to the progress of the infection. The tendency is to the formation of a quiescent focus—the tubercle. There is probably some element in the blood that, together with the stimulating influence of the bacilli, provokes the protective cell proliferation. The bacilli, when set free from a discharging focus, are provided with an inert protective envelope, which is destroyed by the normal tissue fluids. When this happens they are able to multiply, but this multiplication stimulates cell proliferation, and, according to the activity of this process, multiplication is checked. The bacilli are destroyed in part; the rest, through the protecting influence of caseation, remain latent, provide themselves with the protective envelope, and if discharged outward are able to infect another individual. The question of the possibility of producing a specific artificial immunity toward the tubercle bacilli is discussed at length by Smith, who thinks the best results in protective inoculation will be obtained with the use of bacilli killed at a low temperature and from fresh cultures, which can be made at any hospital or sanatorium. These can be injected locally, each injection forming a new radiating focus of immunity, and the fresh culture insuring a more effective preparation. The tendency of infectious diseases, he holds, is toward a balanced parasitism, with reduced mortality, but not necessarily a reduced morbidity. This is due to selective adaptation of both the host and parasite, and this selection will, he believes, go much farther, and we may yet have a type of tubercle bacilli producing only a bronchitis. There are already some indications of this. The effect of a possible immunization of the human race is open to question. Immunization, Smith says, would be an admission that the germ has come to stay, and merely increasing our resistance to the prevailing type would lead eventually to the selective production of more virulent types and a slackening of the usual preventive measures that might eventually cause disastrous effects from the newly-developed more virulent organisms.

Formic Acid.—H. Stern says that formic acid in ten-drop doses has a mild diaphoretic and diuretic effect; this is still more pronounced with twenty-drop doses, and is accompanied with contracting sensations in the pyloric region when the stomach is empty. In large doses (from 3 to 4 c.c., well diluted) on an empty stomach, it causes dryness of the throat, tinnitus, slight vertigo, gastric burning, sometimes mild pyloric spasms, lassitude, slight motor disturbances, and elevation of temperature of from one-half to two degrees, followed in from half an hour to one hour by marked prespiration and diuresis. In doses of from 0.5 to 1 c.c. three times a day for some weeks it acts as a muscular excitant in some instances. No fatal case of formic acid poisoning is on record. The therapeutic uses of formic acid are manifold, but it has been used chiefly as an epispastic. Internally, Stern has used it with benefit in cancer, and thinks it has certainly delayed the fatal issue in a number of inoperable cases. He has often used it in toxicoses of supposedly intestinal origin, and believes it has a distinct antidotal value in these cases. Besides its pronounced antiseptic properties, it exerts a specific influence on the enteric secretion which is lacking in the formates. He has had splendid results with the drug in the secondary and tertiary stages of syphilis. He uses a special iodine-formic acid solution in these cases in gradually increasing doses, carrying

it up to even 3 c.c. of the solution three times daily, but so large a dose is hardly called for and might be injurious to the gastric lining. He thinks this solution especially adapted to the treatment of the nervous manifestations of syphilis. It has also proved the most valuable agent in his hands for what have been called the chronic ulcerative and chronic fibrous types of pulmonary tuberculosis.

Cancer in the United States.—Guthrie McConnell finds from an elaborate study of the statistics of the census of 1900 that while the death rate from consumption has very markedly decreased, that from pneumonia and cancer, especially the latter, has increased during the decade, the ratio of cancer increase being 12.1 per 100,000, and that this mortality is higher in the rural districts than in the cities. It is greater among foreign-born whites than among native whites, but the death rate from this cause is only apparently greater among the former here than in their native lands. Females are more subject to cancer than men, the respective percentages being 63.1 and 36.9. Persons employed in hard out-door labor seem more liable to the disease than those following sedentary occupations. Well-watered and timbered mountainous regions like the northwest coast, show the greatest mortality, and the figures do not support the view that cancer is more prevalent along rivers. No proof is afforded by the statistics of any direct connection between cancer mortality, a prevalence of German population, and beer drinking. Cancer mortality is highest after the sixty-fifth year of life, and after the forty-fourth year is greater among the unmarried of both sexes than the married. The general average at death from cancer is 58.1 years.

A New Protozoan Infection.—S. T. Darling reports a case of apparent miliary tuberculosis, in which, however, instead of tubercle bacilli, there were found vast numbers of a protozoan parasite resembling somewhat the Leishman-Donovan bodies, but differing markedly in certain particulars and in the lesions produced. The organism, when stained with carbol-fuchsin and methylene blue and washed with eosin, appeared as an oval or rounded body with a refractile, non-staining rim, and containing chromatin granules, averaging three microns in diameter and dividing by fission. Flagellated forms were also seen. In the lung smears the parasite was apparently always intracellular, and it seems generally to have a predilection for endothelial and epithelial cells. The lesions produced were scattered focal necroses of liver, spleen, and lymph nodes with foci of catarrhal pneumonia and hemorrhages in the lungs, in which the lungs play a very passive part, there being no leucocytic infiltration of the miliary pneumonic nodules. The infection was a fatal one, no other cause of death being found. For the parasite the designation *Histoplasma capsulata* is proposed by the discoverer.

Misleading Symptoms in Cerebral Disease.—J. A. Stucky reports a case of sarcoma involving the whole right temporo-sphenoidal lobe, associated with and infected by chronic suppurative ethmoiditis, and asks which was the primary lesion. No macroscopic evidence existed of disease elsewhere in the brain. The local symptoms, pain and bulging of the orbit, pointed to trouble in the right fronto-orbital region, but there was aphasia (the patient was right handed), spasm of the right arm and hand, and the tongue deviated to the right. The author asks: Could general intracranial pressure exist without motor symptoms referable to right-sided pressure and also what would have been the result had the sinus disease been eradicated months before?

The Lancet, April 14, 1906.

Some Points in the Treatment of Chronic Bright's Disease.—According to Samuel West, the conditions included under this term are therapeutically reducible to two: chronic parenchymatous inflammation or the later stage of acute nephritis and granular kidney. In the former, it is a mistake to keep the patient too long on an exclusive milk diet. Nutrition suffers and the tissues become flabby and soft. Alcohol and meat extracts should be avoided, also fruits and vegetables which are rich in irritating salts, *e. g.* tomatoes, asparagus, etc. Eggs are allowable. Red and white meats may both be used but should be boiled, not roasted. Fresh air must be allowed in abundance. In granular kidney the conditions are different. In the early stage the patients must live moderate, careful, and temperate lives, be properly clothed, avoid chills and exposure, keep their skin in good action, and the bowels regular. They must avoid alcohol, especially spirits, eschew dissipation of every kind, and live as much as possible in fresh air and sunlight. Even their recreations need not be seriously restricted, provided they are not such as to lead to risky exposure or fatigue. In the intermediate stage when the heart is markedly hypertrophied and the arteries are much thickened, the treatment has to be directed, in addition, to guarding against the accidents that are now specially liable to occur. These are chiefly failure of the heart, rupture of vessels, and inflammatory affections of the kidney itself. A hypertrophied heart has diminished reserves and therefore hypertrophy of the heart is rightly regarded as a pathological condition. It lacks the margin or reserve of power which the healthy heart possesses. Its reserves have been swallowed up in growth, so it is that a hypertrophied heart will give way under strain that would not affect a healthy heart at all. It is therefore especially necessary in this stage to avoid physical or mental strain and fatigue and to watch the heart very carefully. In the third stage, symptoms may be referable to almost any organ in the body, and the kidney may be overlooked. A patient with granular kidney ought to have an arterial tension above normal. If too low it may be raised by digitalis, adrenalin, or ergot and a more liberal diet. If too high, we may give the iodides and nitroglycerin. Caffeine, theobromine, and diuretin will increase the daily output of urine. The author uses pilocarpin freely and cannot understand the prejudice against it. He advances the idea that the kidney may have an internal secretion like the thyroid, though of this fact we have no proof. He says that the administration of renal substance or extracts is in the experimental stage. *A priori*, that treatment deserves serious trial. The results are so far inconclusive. For this there may be several reasons. Many of the cases come under notice too late for treatment of any kind whatever to do much good; the suitable cases would be those in the earlier stages. Then, again, stable renal extracts cannot as yet be prepared, and the extracts to be used must be made fresh as required. Many of the extracts have been made from the kidneys of sheep—that is, from those of vegetable feeders. It may be that the kidneys of omnivorous creatures like the pig would be more efficacious. Using such preparations as he could make or get made, he thinks he has had some good results.

The Influence of the Nervous System and External Temperature upon Certain Circulatory Changes Concerned in the Etiology of Catarrh, Ulcer, and Simple Dilatation of the Stomach, with Suggestions as to Treatment.—Alfred Mantle says that the gastric circulation may become disordered through the central nervous system by the irritation of food and by changes in external temperature, all of which factors may be combined in varying degree. The effect of excitement and worry on gastric functions is well known. Dietetic errors are chiefly manifested in the nerves. Grave circulatory disturbances are excited by gastric irritation. Collapse often ensues and patients are put in desperate straits. Gastric perforation has been simulated in some instances. Some patients with sensitive stomachs are greatly affected by changes in external temperature, being directly affected through vasomotor alterations in the general splanchnic area. When food is taken much blood is attracted to this region with a consequent lessening of the amount in the skin, so that a feeling of chilliness is not infrequently experienced after a full meal. Naturally this happens more often during the colder months. Similar splanchnic congestion follows from malaria and severe burns. Splanchnic statis may lead to hematemesis. In 26 patients with gastric ulcer operated on, 18 acknowledged that they had always had a poor peripheral circulation and had been very sensitive to cold, while 2 out of 6 patients, with duodenal ulcer made similar confession. As to treatment, the great measure is to supply external warmth to the cold parts and the wearing of the proper clothing. Moreover, we should examine the mouth for carious teeth or other sources of infection in all cases of gastric disorder, inasmuch, as already stated, any superficial ulceration of the stomach may become infected by organisms from the mouth and develop into deeper ulceration. It is equally important to treat anemia if present, for its existence will hinder any reparative process.

The Relationship Between Graves's Disease and Acute Rheumatism.—Several series of cases of Graves's disease reported by different authors are analyzed by W. E. Robinson. The pertinent fact running through the various groups is that the salicylates seemed to be of distinct therapeutic value. In some coincident point symptoms were strongly in evidence; in others the family histories suggested an etiological relationship. Out of 127 cases analyzed from Guy's Hospital Reports, 18.9 per cent. gave a definite history of acute rheuma-

tism, while in 9.45 per cent. there was a family but not a personal history of the same disease. The author does not believe that there is in the cases he has studied any evidence to support the toxin theory of Graves's disease. He purposes three questions as worthy of careful consideration by clinicians: (1) Is Graves's disease due to a rheumatic diathesis? (2) Is it due to a toxin or toxins produced by acute rheumatism? (3) Is it an alternative set of symptoms to the more usual articular lesions in acute rheumatism? In other words, is the hyperplasia of the thyroid gland a true rheumatic affection? And though one cannot at once hope for an answer yet it would seem to be a logical deduction from the cases he reports to treat a series of cases of Graves's disease in a routine way with sodium salicylate and compare results with those already published.

British Medical Journal, April 14, 1906.

Painless Labor.—Another case is reported by W. J. Young. He says that most practitioners are familiar with the "physiological anesthesia" in strong women at the height of their pains, but that this is very different from a "painless labor" in the strict sense of the term.

Angina Pectoris Without Apparent Disease of the Heart or Blood Vessels.—A case is reported by E. Curtin which seems to point to the possibility of blood pressure as a cause of anginoid seizures. His patient was a man of 59 years without antecedent history except dyspepsia of two years' duration. The attacks were typical in character, but no evidences of cardiac or vascular disease could be discovered. A diagnosis was made of a cancerous growth of the pancreas with a metastasis on the under surface of the left lobe of the liver. The author believes that the essential condition of the attack was an extreme contraction of the systemic arteries, and especially those of the splanchnic area, probably induced by involvement of the solar plexus in the cancerous growth, and consequent damming back of the blood on the left ventricle, which, owing to the attenuated condition of its walls, became suddenly stretched and perhaps dilated, and therefore unable to bear the stress on its increased superficial area.

Treatment of Tænia.—J. K. Fowler finds that the admission of tænia patients to hospitals gives much better results than does their treatment as out-patients. His method is as follows: (1) The patient is kept in bed. (2) For two or three, or in some cases four, days the patient is given a diet consisting of: Beef tea, 2 pints; Mason's essence, one tin; two rusks; and port wine, 4 oz. During the same period the patient takes tabloids of cascara sagrada (gr. ij) three times daily. (3) On the fourth day (usually) at 5 A. M. haustus sennae co. ℥j; at 9 A. M. a capsule containing ℞xv of the extract of male fern; at 9:15 ditto; at 9:30 ditto; at 9:45 ditto; at 11 A. M. haustus sennae co. ℥j. If by 1 P. M. the worm has not been passed and the head found, a second course of treatment with male fern at intervals of fifteen minutes is begun; to be followed in an hour by a purgative draught. If the head is not found a third course of treatment is prescribed.

Important Symptoms in Diseases of the Eye.—A. M. Ramsay considers this subject under the two headings of disorders of general sensibility and of the function of vision. Of the general symptoms, pain is the most common and the most important. The condition causing it may be inflammatory or non-inflammatory. In the latter circumstance it is often described as neuralgic and is aggravated by the use of the eyes. It may be present apart from such use, and then is mostly unilateral involving some portion of the fifth cranial nerve. Itching may be present, being caused by inflammation of the edges of the lids or by defective metabolism. Photophobia is another common symptom. In phlyctenular keratitis it is the most striking subjective feature. It may be present acutely in retinal asthenopia. In reaching a conclusion by the method of differential diagnosis, the accompaniments of the pain, photophobia, condition of the pupil, high tension, and tenderness on pressure are most helpful. As to disorders of visual function, it may be said that sudden loss of sight when bilateral is generally due to some toxic cause, most commonly by anemia. Embolism of the central artery of the retina destroys sight without a moment's warning; but in nearly every case one eye only is affected, and ophthalmoscopic examination leaves no room for doubt regarding the diagnosis. Again, sight may be completely lost immediately after a blow on the forehead; but in that case ophthalmoscopic examination reveals at first nothing abnormal, the reason being that the optic nerve has been injured through fracture of the bones at the optic foramen, and not till some weeks after the accident can atrophy of the optic disk be recognized. When the blindness is sudden, but incomplete, much information is obtained by testing the field of vision. A blank in a portion of the periphery is due in all likelihood to a detachment of the retina, or to an extensive hemorrhage into the vitreous; should the patient complain that all lights seem to be blood-red in color, the latter lesion is almost certain to exist. When there is a failure to recognize the various colors in the central portion of the visual field, the fault may be due to overindulgence in alcohol or tobacco. A patient may see well during the day but be practically blind after sunset. This symptom is almost pathognomonic of that form of retinal degeneration known as retinitis pigmentosa. Other disturbances may be referable to changes not in the eyeball but in the ocular nerves, optic tracts, and cortical visual centers. Syphilis is the chief cause of ocular paralysis.

Berliner klinische Wochenschrift, April 9, 1906.

A Case of Acute Bromine Rash in Exophthalmic Goiter.—Uhlich describes this case, which was that of a woman with pronounced exophthalmic goiter, for whom a bromine combination was prescribed. On the first day after beginning the remedy she developed an eruption, but as she did not recognize its origin the use of the drug was continued for a week. The rash began with small red spots which rapidly enlarged, itched, and finally developed into vesicles. In some instances these became confluent and the whole rash somewhat resembled the antipyrin exanthem. The eruption was most abundant on the backs of the hands, about the neck, and the eyebrows. Acute bromine eruptions are very rare, the usual skin lesions produced by the drug being the characteristic acne which follows its long continued administration. In this instance the patient's susceptibility was no doubt due to the extremely irritable nature of her skin, which rendered her an excellent subject for the demonstration of urticaria factitia.

Torsion of the Omentum in Incarcerated Inguinal Hernia.—Litthauer says that the case which he reports is the second instance of this kind described in the literature. The patient was a woman fifty-three years old who had suffered from an inguinal hernia for several years. She was brought into the hospital because of incarceration, and on opening the hernial tract a large mass of omentum was revealed which was in a loop so that no free end presented. As it was impossible to liberate any free extremity a laparotomy was done, and it was found that the omentum had been turned about its axis one hundred and eighty degrees three times not far from the transverse colon. Of the distal portion a considerable part formed the loop which had been found in the hernial sac, while the tip was very much swollen and congested, and had therefore formed an obstacle which had made it impossible to draw the free end down through the hernial ring. The patient made a good recovery, which was somewhat protracted, however, through a thrombosis of the left femoral vein.

Münchener medizinische Wochenschrift, April 10, 1906.

The Incision in Laparotomy.—Heusner says that the first consideration in the laparotomy incision is perfect asepsis with the avoidance of contact with irritating fluids, superfluous manipulation, or intraperitoneal bleeding. The incision should be no larger than necessary because with the increase in size there is greater danger of the formation of adhesions and of infection. The nerves of the muscles must be avoided, as otherwise relaxation and stretching of the affected region will follow. In order to secure as firm a scar as possible it is advisable to place the incision so that it shall pass through firm and resistant portions of the abdominal wall, preferably where several layers exist rather than through thin and weak regions. Finally, as Kocher has pointed out, the skin incision should, where possible, coincide with the skin fibers of Langers, as in this way there is less gaping of the wound and better cosmetic results are attained. He then reviews the advantages and disadvantages of the different incisions most in use, and finally states that he has himself in a number of instances made use of transverse incisions through the rectus muscles. These are made slightly curved upward or downward according as they are placed above or below the umbilicus. At the level of the umbilicus the incision is made horizontal. The author considers that the scars following this mode of operation are firmer than those obtained by incisions in the median line.

The Indications for Operation in Appendicitis.—Krecke is a warm adherent of the doctrine that early operation offers the best chance of cure in appendicitis,

but he believes that there is a certain small percentage of cases in which a single, very light attack is experienced without being followed by recurrences. Such attacks do not, of course, demand operation, but it is extremely difficult to distinguish them from the severer type. In making the differential diagnosis between these simple and severe forms, the necessity for which presents itself in every instance, abdominal rigidity furnishes the most valuable single sign. If there is no rigidity or other disquieting symptom the existence of the mild form of the disease may be assumed, but if there is any rigidity whatever it is an imperative indication for operation. The elevation of the pulse rate above 100 is usually a sign of destructive appendicitis and demands prompt operation, but a low pulse rate does not justify the assumption of a mild attack. The behavior of the temperature is not of great value in determining the variety of the disease. Increased rapidity of respiration and the appearance of the costal type of breathing are always unfavorable signs. A single unfavorable sign is of greater significance in estimating the gravity of the case than four favorable signs. Having made the diagnosis of destructive appendicitis the operation should be performed within the next two hours.

The Treatment of Inflammatory Conditions of the Skin with Hot Baths.—Richter, who has a very large accident practice among miners, states that he has for some years used a method of treatment for infected wounds, contusions, furuncles, etc., which while apparently old-fashioned in conception is yet in accord with the teachings of modern bacteriology and hemology. It consists in having the patient place the injured member several times a day in a bath of water as warm as it can be borne, in which it is kept for at least a half to one hour. In view of the doubtful cleanliness of the vessels often used for this purpose by the patients, the author usually directs that half a tablespoonful of soda be added to each liter of water. When the injury is situated in a region that cannot be immersed in a bath he applies wet compresses which are kept hot by means of hot water bottles. The results obtained by this method are excellent, and Richter ascribes its efficacy to the fact that marked local congestion is caused, as in Bier's method of hyperemia treatment, and that through the abundant supply of blood and lymph brought to the affected region the body is enabled to cope successfully with the infection.

Deutsche medizinische Wochenschrift, March 22 and April 12, 1906.

Asepsis in Operation Wounds.—Döderlein has carried out an extensive series of observations intended to determine the degree of asepsis attained in the course of operative work. For this purpose about five thousand bacteriological tests were made in the course of one hundred laparotomies, cultures being made from all of the instruments, fluids, hands, and other objects coming in contact with the wound, as well as from the interior of the wounds themselves. It was found that even when the most rigid precautions were used a considerable number of the cultures were positive, and it was finally concluded that the most important source of contamination was furnished by the skin of the patient. After considerable experimentation with various forms of coating for the skin Döderlein decided that the most practical and serviceable method was to paint the area to be operated upon with pure tincture of iodine, after which a solution of India rubber in ether and benzin was applied. As soon as dry a little sterilized talcum powder was rubbed over the surface in order to prevent stickiness, the superfluous powder being brushed off again. When operating in this way not only the bacteriological tests showed great improvement, but advantages from the clinical standpoint, such as a lessened tendency to postoperative intestinal disturbances, were also noticed. The author warmly commends to all operators the practice of from time to time making systematic bacteriological tests of all the elements that can possibly enter into the question of wound contamination.

Local Anesthesia in the Surgery of the Internal Ear.—Neumann says that the prevalent belief that operations on the internal ear cannot satisfactorily be carried out under local anesthesia is erroneous, and describes his method for producing a painless operative field. The point of the injecting needle is inserted into the upper wall of the cartilaginous portion of the meatus about .5 to 1 cm. from the beginning of the bony canal. This point is determined by the fact that on moving the external ear back and forth a sharp fold appears at the junction of the movable cartilaginous portion of the meatus with the fixed portion of the canal. The needle is carried obliquely upward to the bony surface and the anesthetic solution, warmed to forty-five degrees C., is injected under the periosteum. The procedure is almost painless, but if necessary may be carried out under ethyl chloride anesthesia. In order to anesthetize the mastoid process for operations in this region the needle is carried vertically down the bone, is then inclined obliquely, and 3 to 4 c.c. of the fluid solution, warmed to 50° C., are injected. If a radical operation is to be done these methods of anesthesia are combined. The author prefers a solution of cocaine with the addition of some one of the adrenal preparations, to all the other local anesthetics.

Surgical Treatment of Sciatica.—Pers believes that the surgical treatment of this disease might with advantage be resorted to more frequently than is usually done. He does not consider the old operation of stretching the nerve as the proper one, however, and ascribes the disfavor into which the procedure has fallen to the bad effects produced by this method of operating. In two cases of severe sciatica that he was called upon to treat, a permanent cure was effected after all the ordinary remedies had been used without avail, by exposing a very considerable portion of the nerve and removing from its surface with forceps and gauze the fine network of pink connective tissue strands which surrounded it. These the author regards as the results of a perineuritis attending the neuritis, and he suggests that in obstinate cases the affected portion of the nerve be freed from these adhesions through an incision which must be made long enough to extend to the point where the nerve begins to be normal in appearance again.

Premenstrual Elevations of Temperature.—Riebold made careful observations in this respect on a series of 2,000 patients who were under hospital treatment on an average for thirty days. Only such instances were included in the figures in which there was an elevation of temperature of at least .5° C. on one of the three days preceding the period or on the first day of the period, without there being any discoverable reason for the fever. The temperatures of the patients were taken for at least six days previous to this premenstrual period, and the maximum temperature of this time was taken as the basis for estimating the elevation. Eighty-five cases were discovered in which premenstrual fever of this sort was noted. Most of the patients were phthisical, but a considerable number suffered from other affections. The author considers that such fever is never observed in entirely healthy women, and that when it does occur it indicates an irritation of some already existing, possibly latent, disease focus. It is the result of the stimulation of the vital processes in general, which is the normal concomitant of ovulation. While healthy women do not manifest any heightened susceptibility to disease during the premenstrual period, an already diseased organism is in greater jeopardy than usual at this time. The cessation of a previously existing tendency to premenstrual fever is to be regarded as a favorable prognostic omen in pulmonary tuberculosis, whereas it is a distinctly adverse sign if the symptom appears in any severity in the course of tuberculous disease.

A New Test for Santonin in the Urine.—Neuhaus suggests the following test: Several drops of Fehling's solution are added to a few c.c. of the urine in question. If santonin is present a dark green color appears, which changes to dark violet-red on addition of more of the reagent. If an acid is added, the color changes to light green. Acetic acid is the most suitable for the purpose. The reaction can always be obtained in the urine of children that have taken the ordinary doses of santonin, but in the case of adults the amount of the drug ingested must have been somewhat larger, corresponding to the greater body weight. No other drugs appear to give rise to this reaction, with the exception of rhubarb, which produces a dirty green color, but does not pass through the preliminary violet-red stage. The commonly used test for santonin in the urine, which consists in the production of a red color on the addition of caustic alkali, is more sensitive than the reaction with Fehling's solution.

Potassium Permanganate as a Hemostatic.—Vörner recommends potassium permanganate as a hemostatic of exceptional efficiency. He uses it in a strong solution, in a powder (50 per cent.), or in a paste with vaseline (1 to 3). It is most useful in hemorrhage following minor operations, excision of small tumors, or in epistaxis. Usually one application will control the hemorrhage. There is little irritation attending its application, it does not destroy the tissues, and its antiseptic properties make it especially valuable.—*Clinical Review.*

Book Reviews.

Manuale delle Malattie dei Bambini. Di John Madison Taylor, A.M., M.D., Professore delle Malattie dei bambini presso il Policlinico di Philadelphia, ecc., e William H. Wells, M.D., Professore aggiunto di Ostetricia e malattie dell' infanzia nel Policlinico di Philadelphia, ecc. Traduzione Italiana sulla seconda edizione, interamente riveduta ed ampliata. Per il Dr. Mario Flamini, Assistente nella Clinica Pediatrica e negli Ospedali di Roma. Con Prefazione del Prof. Luigi Concetti, Direttore della Clinica Pediatrica di Roma. Con Note ed Aggiunte del Prof. Francesco Valagussa, Aiuto e Docente nella Clinica Pediatrica della R. Università di Roma.

The translation of another American textbook into Italian is but a sign of the constant advance of American medicine and surgery, and the inevitable recognition of this advance abroad. In this review it is not our purpose to offer a criticism of the now standard work of Taylor and Wells, but rather to give a brief account of the Italian version of the book which lies before us. The Italians as a rule read medical French fluently enough, so that the works of Comby and other pediatrists are accessible to them. The German treatises, those of Gerhardt—now out of date—Henoch, Baginsky, etc., have appeared in excellent Italian translations. "English and American pediatric literature," to quote from Professor Concetti's introduction to this present volume, "is rich in excellent treatises from the pen of masters of his branch who are the products of the model hospitals so munificently provided by private charity in the Anglo-Saxon countries." The classical lectures of West, the treatise of Ashby and Wright—both known to students of the generation just arisen—and now the work of Taylor and Wells, a book current among the rising medical men of this country, have been translated into Italian. Professor Concetti, the director of the pediatric clinic at Rome, pays a tribute to the American authors, and speaks appreciatively of the clearness of exposition and the practical character of the work of Taylor and Wells. Especial comment is made on the minute thoroughness of the chapters on infant feeding, intubation, etc., subjects particularly well developed in America.

Some changes, however, were found necessary for the benefit of Italian students. Diseases that more commonly occur in Italy have been treated with a greater profuseness of detail, and some diseases which Taylor and Wells omitted, as Riga's sublingual fibroma, have been added. Rheumatism has been placed where it etiologically belongs—among the infectious diseases—and not among the constitutional diseases, where it appears in the American book.

Verhandlungen der Deutschen Röntgen-Gesellschaft. Band I. Verhandlungen und Berichte des Ersten Kongresses zu Berlin vom 30 April bis 3 Mai, 1905. Hamburg: Lucas Gräfe & Sillem, 1905.

The first volume of the report of the first Congress of the Röntgen Society gives some 250 large pages of most interesting matter in all departments of *x*-ray work, and with the succeeding volume should form a most valuable addition to the literature of a subject growing each day in interest and importance. The great amount of serious work here represented speaks highly for the rank which *x*-ray investigators are taking in the scientific world. English and French as well as German articles are included.

Laboratory Guide in Experimental Pharmacology. Directions for the course given at the University of Michigan. By Charles W. Edmunds, A.B., M.D., Instructor in Pharmacology in the University of Michigan, and Arthur R. Cushing, A.M., M.D., Professor of Pharmacology in University College, London, and late Professor of Materia Medica and Therapeutics in the University of Michigan. Ann Arbor, Mich.: George Wahr, 1905.

This little book is a guide to the student in the pharmacological laboratory at the University of Michigan. It covers the elements of experimental pharmacology, including the modes of action of the principal groups of drugs, and also a certain amount of practical pharmacy, which is comprised in the course given by the authors. While the book essentially represents the methods of teaching at one particular laboratory, and does not attempt to be a systematic treatise on experimental pharmacology, the authors are teachers of such recognized authority that their manual may serve as a guide in other teaching laboratories—with such modifications as local conditions may demand.

Laboratory Manual of Physiology. By Frederick C. Busch, B.S., M.D., Professor of Physiology, Medical Department, University of Buffalo. New York: William Wood & Co., 1905.

This little volume contains the technique of physiological experiments such as are best adapted for the use of medical students. The subjects covered include the physiology of muscle and nerve of the central nervous system, the blood, the circulation, the secretions and excretions, sensation, respiration, and vision. Practical subjects are given prominence wherever possible, *e.g.* thyroid feeding, the influence of drugs on the eye, action of drugs on muscle, etc. Descriptions of apparatus have been largely omitted, and the method of experimenting is given, leaving the deductions to the student to work out for himself. Dr. Busch's manual presents a valuable contribution to the pedagogics of physiology in the medical school, or, for that matter, the biological course of the academic college.

The Animal Parasites of Man. A Handbook for Students and Medical Men. By Dr. Max Braun, Professor of Zoology and Comparative Anatomy, and Director of the Zoological Museum of the University of Königsberg, Prussia. Third Enlarged and Improved Edition, with 294 illustrations in the text. Translated from the German by Pauline Falcke. Brought up to date by Louis W. Sambon, M.D. (Naples), Lecturer at the London School of Tropical Medicine; Honorary Member of the Manila Medical Society; Member of the Société de Médecine Tropicale, Paris; The Royal Medical and Chirurgical Society, etc.; and Fred V. Theobald, M.A., Vice-Principal and Economic Zoologist to the South Eastern Agricultural College; President of the Association of Economic Biologists, etc. New York: William Wood and Company, 1906.

It is a comforting thought that the one hundred and ninety or so animal parasites, exclusive of the countless flies and mosquitos, described in this interesting book, do not all inhabit any one man at any one time. We all entertain some, and are liable to harbor any, especially if we wander into the tropics to take up the white man's burden, hence the interest and value of this important work. Braun's treatise has long been recognized as the authority in this branch of medical research, and it is a matter of congratulation that it is now accessible to English-speaking students. After a brief introduction on parasites in general and their origin, the author devotes the rest of his interesting book to the animal parasites of man. The first chapter is on the protozoa, the immense importance of which, as the *contagia viva* of many of the scourges of mankind, especially in tropical and semitropical regions, has only recently been recognized and is even yet not fully appreciated. Following this are chapters dealing with the platyhelminthes or tapeworms, the nematodes or threadworms, and the acanthocephala (echinorhyncus). Then, after a brief chapter on the leeches, the arthropoda (including the itch mites), ticks, lice, flies, and mosquitos, occurring as temporary or permanent parasites, are treated of at length. Here again, the importance of several of the families of insects as intermediate hosts of many of the pathogenic protozoa is of comparatively recent recognition, but a knowledge of their habits and of their agency in the propagation of malaria, yellow fever, and other diseases is indispensable to the student of tropical diseases.

Dr. Braun handles his subject with Teutonic thoroughness and attention to detail, yet there is nothing dry in his treatise; the work has indeed all the interest of one of the popular nature study books without their superficiality. It is profusely but not superfluously illustrated with well-executed wood-cuts in the text. We know of no work of the kind, in the English or any language, to compare with this in minuteness of detail, clearness of description, interest, and authoritativeness. The only criticism we have to make is that little is said regarding the symptoms occasioned by the animal parasites, or their treatment, beyond a few remarks on prophylaxis. The author is a zoologist and does not attempt to encroach upon the domains of the clinician or the therapeutist. In its own field of animal parasitology, however, the treatise is without rival.

Oliver Wendell Holmes and the Contagiousness of Puerperal Fever. An address delivered at Marlborough, Wiltshire, to the Trowbridge Division of the Bath and Bristol branch of the British Medical Association, October 28, 1905. By Charles J. Cullingworth, M.D., F.R.C.P., D.C.L. (Hon.), Durham; LL.D. (Hon.). Aberdeen; Consulting Obstetric Physician to St. Thomas's Hospital, London. With Portrait. London: Henry J. Glaisher, 1906.

Dr. Cullingworth's admirable address should do much to remind the profession that a countryman of ours had insisted on the contagiousness of puerperal fever and published an essay on the subject several years before the ill-starred Semmelweis had made his earliest observations on the malady. The address has already been discussed at length in the Medical Record, November 25, 1905, at which time the hope was expressed that it might be republished in this more accessible and permanent form.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held April 6, 1906.

DR. SAMUEL LLOYD IN THE CHAIR.

Fractures of the Tarsus.—Dr. LEONARD W. ELY presented six cases illustrating points to be brought out in his paper.

Dislocations of the Metatarsals.—Dr. Ely also presented this case.

Case of Congenital Dislocation of the Patella.—Dr. CHARLES GOODMAN presented a boy, 13 years old, with a congenital dislocation of the patella. His frequent tendency to fall prevented him enjoying games with other boys in which running or jumping was a feature of the sport. The right patella was very movable and the fingers could be readily inserted underneath the inner margin of the bone when the limb was extended. Upon flexing the right knee the patella overrode the external condyle and by voluntary contraction of the quadriceps the boy was able to dislocate the patella completely outwards. There was no deformity of the femur.

Internal Hernia, Strangulated through Omental Slit.—Dr. Goodman presented this case. (See page 713.)

Omental Hernia, with Suppuration; Operation.—Dr. FORBES R. MCCREERY reported the case of a man, 25 years old, a groom, who had been kicked by a horse eight years ago in the right lower quadrant of the abdomen. At first he felt some pain and was about to continue his work when he began to vomit. The abdominal wall became very hard, but there were no lumps or discoloration. At the end of one month he was sent to the hospital. The vomiting and abdominal rigidity persisted and it was thought he would die. There was no pain. The abdomen was blistered and he was bandaged. In about two months he recovered sufficiently to leave the hospital. When he rode horseback he occasionally had a "stitch in the side, near the kidney." Five or six months after the kick a lump appeared in the right inguinal region which worked lower until it entered the scrotum. He never wore a truss. His health failed greatly. On December 2, 1905, the mass was found to be surrounded by old and dense cicatricial tissue. While attempting to separate the mass an opening was made into a cavity containing grumous fluid; a number of small collections of pus were thus opened. The entire mass of omentum seemed to be riddled with abscesses. The pus was odorless and no tubercles were seen. The omentum was tied off in sections, the stump secured just inside the internal ring, the sac was sewn to the skin, and a cigarette drain passed to the bottom of the large intraabdominal abscess cavity. Recovery was satisfactory. The pathologist reported that interference with nutrition was chiefly responsible for the condition of the omentum. There was thickening of vessel walls, and some small foci of calcification in dead tissue. Smears of pus failed to show bacteria.

Perineal Lithotomy for the Successful Removal of a Vesical Calculus of Unusual Size in a Young Child.—Dr. C. C. SICHEL said that this negro child, 2½ years old, was admitted to the hospital for a small umbilical hernia. A few months previous the child had been admitted for rachitis and improved under treatment. The boy was circumcised, but was returned to the hospital because of an infected foreskin. Much pus was found in the urine and the child almost went into convulsions at urination. The prepuce healed, but the pain remained. The amount of pus increased and bladder drainage was instituted. No stone was found, although looked for. The child improved, the pus decreased, and pain and resulting spasm were relieved. Dr. Sichel found a baby well nourished, but with still some pus in the urine. A small opening in the perineum persisted and an umbilical hernia was present. When the abdomen was opened a greatly distended bladder was found with a large calculus resting in its neck but freely movable. After completing his operation for the hernia, he closed the abdominal wound and then enlarged the perineal opening and inserted a broad sponge forceps and, after some difficulty, delivered the calculus. Its shape was oval; its long circumference was 3¼ inches and short circumference 2¾ inches. A calculus of this size was, as a rule, best removed by the suprapubic route. But in this case the perineum had been opened; and again, desiring primary union for the hernia operation, he believed the dangers of a general infection of the peritoneum would be lessened by the perineal lithotomy.

Cases of Fracture.—Dr. CHARLES A. ELSBERG presented several cases to illustrate his paper. One was a fracture of the femur and both bones of the leg in which he had used the aluminum cylinders. There resulted no shortening of the limb.

Report of a Case of Heteroplastic Ovarian Grafting, Followed by Pregnancy and the Delivery of a Living Child.—Dr. ROBERT T. MORRIS presented this communication. (See page 697.)

Dr. C. G. CUMSTON of Boston referred to a recent article by Simon in which it was stated that microscopically two stages followed ovarian grafting. The ovary, during the first part of the time after grafting the ovary, was only nourished by the interstitial fluids of the surrounding tissues. The cortex alone retained its vitality because the fluids could not reach the central portion of the gland. The medullary zone degenerated and disappeared while a cicatricial process became established. At the end of three or four months the ovary regained its normal circulation. The various ovarian elements showed modification in their histological structure, depending upon these different nutritive phases. The interstitial cells gave evidence of changes distinctly demonstrating the influence of the nutrition of the organ, and immediately after the graft they lost their power of differentiation, their boundaries disappeared, while their cell bodies considerably diminished in size. At the end of three months, when their nutrition was again normal, they again gave evidence of functional activity, and took on the appearance characteristic of their physiological state. In view of these facts a properly performed hetero-transplantation of an ovary might result in fecundation and pregnancy. The corpus luteum seemed to him to have considerable bearing on the question of future pregnancies after grafting had been done. Enough work had been done in the study of the relationship between the ovaries and metabolism generally to show that the ovary possessed an internal secretion, and that the influence of the ovary upon the genitalia and body as a whole was due to its action and not to the presence of sympathetic ganglia in the hilum of the gland. Fraenkel had concluded that the corpus luteum was a ductless gland and provided an internal secretion which presided over the nutrition of the uterus and the imbedding of the fertilized ovum, and in the absence of fertilization of an ovum the internal lutein secretion excited the menstrual flow. He had used the corpus luteum of a cow as a therapeutic agent in cases of threatened abortion. The lutein substance was given to stimulate the growth of the trophoblast, upon which the process of successful imbedding depended. Fraenkel was satisfied with the results obtained in fifteen cases. So strongly had the view gained acceptance on the continent that the growing trophoblast was dependent upon the corpus luteum that clinicians were endeavoring to check conception by inhibit-

ing the growth of trophoblast by biochemical means, an antilutein extract being used for the purpose. The lutein tissue found around atresic follicles was held to be totally different in origin to that found within the theca of the true corpus luteum, some writers holding that the former was of connective tissue origin and the latter derived from epitheleum. After extensive investigation Fraenkel decided that the *"glanda interstitiella"* was inconstant and very variable. It did not serve any important or general fuction in the human body. Subsequent to its rupture the corpus luteum was a hematoma lined by convolutions of lutein tissue. This tissue consisted of decidua-like cells held together by strands of connective tissue which carried vessels derived from a vascular tunic upon which the cells lay. This tunic was the theca interna; it surrounded the entire yellow body; it represented the old tunica fibrosa, but during the process of maturation of the Graafian follicle it had become highly vascularized and cellular. Internal to the lutein cells, and lying immediately upon them, was a membrane of variable thickness spoken of as the tunica propria by some and as the basal membrane by others. After discharge of the liquor folliculi and escape of the ovum the delicate new capillaries of the theca interna suffered disruption, blood escaping from them to fill the space previously occupied by the liquor folliculi. Thus a hematoma was formed, and it was in this stage that we generally met with a corpus luteum in the human ovary. He then described the process by which the corpus luteum disappeared. Islands of lutein tissue might escape destruction. In the study of lutein cysts a review of the degenerative stages of the ruptured corpus luteum had been almost barren of results. In studying the developmental processes which preceded rupture there were many difficulties. Of the sixty to eighty thousand primitive ova, only 150 to 200 were said to ripen, and it was a rare chance that provided one with a healthy human ovary. The ovum being a very delicate cell, it may suffer from preparation of the tissues for the microscope, and thus present appearances that were misleading. With regard to the origin of the lutein cell, it could be seen to arise from the connective tissue cells of the vascula theca interna outside the basal membrane of the stratum granulosum. He endeavored to show what was assumed to be a transition of the ordinary connective tissue cells into the large decidua-like cells which made up the large convolutions of the yellow body. He had worked on the assumption that the presence of lutein tissue in the theca interna of a small follicle was not of necessity a pathological phenomena, but that this tissue occurred during the healthy maturation of the follicle, and was in fact a progressive stage in its development. He was not prepared to say at what point in the development of the follicle the lutein cell was due to make its normal appearance, and in the same way at what time the granulosa normally broke up and no longer existed as a complete ring had not been demonstrated. He described lutein cysts and said that when a lutein cyst developed alongside of any other cystic space a complication cyst arose. In large islands of displaced lutein tissue lymphangiectases occurred, and by distention of these spaces nonepithelial lutein cysts arose. The possibility of transplantation of ovaries was now demonstrated beyond a doubt. According to Schultz, both in young and in almost grown animals the ovaries became attached in their new position, whether this were the peritoneal cavity of the same female, of another female, or of a male, or of the same breed, or of a female of a different breed. On other females of the same breed transplanted ovaries of mammals could give off eggs and form corpora lutea; on males of the same breed such ovaries could develop ripe eggs up to forty-two days, and show such after one hundred and seventeen days; on females of other breeds such ovaries exhibited, in the first eight days, no difference from ovaries transplanted on females of the same breed; the mode of healing and development corresponded in the animals investigated to the phenomena described by Ribbert, and in ovaries transplanted to males eggs could be demonstrated in the root, and tube-formed processes crowding from the germinal epithelium downward into the tunica albuginea. At the same time changes took place that at least stimulated the embryonic condition. The transplanted ovarian tissue appeared not to be injuriously influenced either by the blood of the male or by any secretion or other influence from the testicles, at least in the short time covered by the experiments. Transplantation did not operate to produce any unusually rapid growth in ovarian tissue, as might possibly be expected. Dr. Cumston suggested that this subject be followed up by such experiments as implantation of ovaries in a female of another breed whose ovaries had been previously removed, and that breeding experiments be then carried on with the male of the same breed.

Dr. E. B. Cragin said that knowing Dr. Morris's care in experimental work and technique, he would be inclined to take his statements as facts simply because he said so. Still there were a number of tests to be applied to the case before accepting it, and he wished to speak on three things that Dr. Morris had laid particular stress upon, as follows: (1) The condition of the ovaries at the time of removal. It was reported that no graafian follicles were found by the pathologist at the time of its removal, and, it seemed to him, more light should have been thrown upon this statement by the pathologist, especially regarding any developing Graafian follicles. (2) Symptoms presented at time of removal. It should be remembered that a woman might have an absence of menstruation for a long period of time and yet not attain the menopause for a number of years later. There was no question but that the ovaries from a woman who was not menstruating, or who had not menstruated for seven years, might have at the time of removal a recent corpus luteum, showing that ovulation had taken place in spite of amenorrhea existing for seven years. Therefore more light upon this condition of the ovaries was needed in order to decide that the ovaries were unable or incapable of producing ova successfully. (3) Method of removal of ovaries. He said that Dr. Morris laid stress upon the fact that the ovaries were removed by the angiotribe, but Dr. Cragin could not help feeling that possibly there was a little ovarian tissue in the stump. We did not know all that we should know regarding the antomy of the ovarian tissues, but he believed that some of this ovarian tissue might have been left behind in spite of the use of the angiotribe. He said that a few years ago a woman came to him with an ovarian cyst on one side and a large cystic ovary on the other. Just before taking the anesthetic she said she would rather die than be made an "it." He removed both ovaries, and on examining the smaller one found that there were small portions which appeared healthy, and these he stitched in the broad ligament in the horns of the uterus. She was told that she was not an "it." She had menstruated irregularly ever since. Personally he believed that Dr. Morris's case would stand the test, and that he ought to be congratulated in contributing something to the cause of science.

Dr. Henry C. Coe expressed the highest admiration for the reader's successful work. The case was so carefully reported and the technique was so admirable that there seemed to be no question as to the scientific value of the communication. However, as criticism had been invited, the speaker wished to refer to certain lacunæ which should be noted. The report of the pathologist

was not as thorough as could be wished in a case of such importance, as it was not made clear as to whether the ovaries were cirrhotic as the result of previous inflammation, or had simply undergone normal atrophy. The statement with regard to the condition of the Graafian follicles was vague and unconvincing. The age of the patient, and the fact that the uterus had not undergone the usual climacteric atrophy, would seem to show that the case was one of suspension of the ovarian function rather than of premature menopause. Still the fact remained that the patient had not menstruated for a long period and that there was every reason to suppose that the flow would not have returned. Whether she had ovulated or not during this time was doubtful. The speaker called attention to the well-known type of amenorrhea in young women who became unusually obese, with or without the disturbances usually attending the normal climacteric. In such cases he had known menstruation to return and to recur regularly after it had long been suspended, as the result of reduction in weight, local stimulation with electricity, etc., though he could not recall an instance in which pregnancy had followed the renewal of the ovarian function. He had had no personal experience with ovarian grafting, but had frequently noted that in conservative operations upon the ovaries, where only a small portion of an ovary had been left, without disturbance of its vascular supply, that there was a decided tendency to atrophy or to cystic degeneration, and that menstruation was often irregular or ceased entirely. As the reporter had stated, the results after grafting had been so uncertain that there was so much the more reason to congratulate him on the brilliant result which had followed after so many previous discouragements. While the operation must have a very limited sphere, it seemed as if in this instance the highest judgment and skill had been exercised, both in the selection of a proper case and in the manner of handling it.

Dr. Herman J. Boldt said that while he was of the belief that it had not been established that the patient upon whom Dr. Morris operated had premature menopause, due to destruction of ovarian tissue—the pathologist's report being practically useless because no serial sections were made—the fact that there were no evidences of functionating ovarian tissue in the sections made by no means proved that there was no functionating ovarian tissue present; however that might be, the fact remained that, whether functionating or not, the ovaries were removed. Knowing of the case and seeing the operation performed, he did not think it likely that any ovarian tissue was left behind. It was most probable and most positive that the subsequent menstruation was established and caused by the ovarian tissue engrafted from one patient to the other. He said he was reminded of some cases he had had under observation, a mother and three sisters in one family, all four presenting from six months to two years between menstruations. Two of these sisters had families. This showed the possibility of not having menstruation and yet ovulation might occur. Personally he did not believe that one should sacrifice any organ apparently normal.

Dr. Robert H. M. Dawbarn, referring to Dr. Morris's statement of future work he was to be engaged in, injecting the blood of one rabbit into the blood of another, with the idea of establishing tolerance, said that he had heard recently from Surgeon W. F. Arnold, U. S. N., who told him of a communication received from Metchnikoff's laboratory which had a direct bearing upon this work. It was found that a small amount of blood from the male animal injected beneath the abdomen of the female animal rendered her sterile, so far as that male animal was concerned. It was tried on dogs and other animals, and found to be true in every instance. This, Dr. Dawbarn said, opened up a new field for both beneficial as well as dangerous work.

The Operative Treatment of Fractures, with a Description of a New Method.—Dr. Charles A. Elsberg, after referring to the difficulties encountered in devising means of holding fragments in position by suture or otherwise, said that an ideal splint must be strong, of a material which could be molded into any shape desired, must be easily sterilizable, should be easy of introduction, should tightly fit in the medullary cavity and fill it entirely, should have the form of a cylinder so as to allow the callus to grow through its lumen, and it should have perforations so as to allow the circulation of fluids from the outside to the inside of the cylinder; and it must be of a material which was well borne by the tissues and must, if possible, stimulate the formation of new bone; also, it should be absorbed after it had served its purpose. He believed that all these requirements would be fulfilled by the absorbable aluminum cylinders, samples of which were presented. They were made of pure aluminum, could be easily sterilized by boiling in 1 per cent. lysol solution, and, from his experiments on animals, would be absorbed in the human body, he believed, in about one year, on the average. The form that the aluminum took in going into solution was, in all probability, aluminum hydrate, a salt that had antiseptic powers, and, from his experience, he believed that when the plates became infected the metal was able to sterilize itself. In the four cases in which he had used the aluminum cylinders thus far, the results had been very satisfactory; there were two cases of fracture of the femur, one of fracture of the humerus from a gunshot wound, and the fourth was a case of compound fracture of the phalanx. In short, his experience with the aluminum cylinders, although small, had impressed him with the favorable results obtained, the firm union, the perfect immobilization, aseptic healing, and no shortening.

Dr. Howard Lilienthal had watched the treatment of two of these cases, which occurred in his service, and corroborated all that had been said by Dr. Elsberg, and he believed that this was a decided contribution to the surgery of fractures.

Dr. Robert H. M. Dawbarn told of the Gorham Silver Company making hundreds of soap dishes of aluminum which became useless because the alkali ate a way through the bottom of the dishes. Having in mind the alkalinity of the blood, it occurred to him that it might be a good thing to try this absorbable aluminum in the adjustment of bones, and he had used it with admirable results in two cases; in both he had used aluminum staples. The metal magnesium had been tried in the form of staples, but it was found to be less absorbable, although less expensive. He had tried magnesium staples in a case of non-united fracture of the radius and ulna. Dr. Elsberg's plan he believed to be the preferable one, for the method by staples was not so easy as it sounded. With regard to technique, he thought it might result in as much good if the cylinder was made to fit with moderate snugness, and not so tight. Celluloid also had the property of being rigid and being absorbable, and he reported a case of fractured nose in which this had been used but was absorbed in a short time, to the discomfortiture of the patient.

Dr. A. W. Berg questioned the value of any mechanical contrivance in cases of non-union in bone. He referred to two cases of non-union following fracture of the humerus seen during the past year, in one of which the aluminum cylinder was used without success. The *x*-ray showed the cylinder still in place. Unless one learned the cause of the non-union no good results would follow the use of intermedullary splints or other contrivances.

Dr. Elsberg said that in the case referred to by Dr. Berg the cylinder did not fit tightly into the narrow cavity; these cylinders, if they were to be successfully employed, should fit fairly firm, and be forced gently into place with a wooden hammer.

Fractures of the Tarsus.—Dr. Leonard W. Ely read this paper. In it he reported fourteen cases of fractures of the tarsus, eleven of the calcaneum, and three of the astragulus. All of these were old cases and only two or three had been diagnosed at the time of injury. The histories given were quite characteristic, all fractures having been produced by a fall from a considerable height, landing on the feet; the patients had then been carried home and had been laid up in bed for a number of weeks, usually with a diagnosis of sprained ankle or bruise. Afterward they complained of pain and stiffness in the heels. Examination showed a peculiar thickening under the malleoli, with obliteration of the concavities, and lessening of the distance between the external malleolus and the sole, usually a peculiar eversion at the ankle joint. Most of the patients recovered, with a fairly useful foot. The treatment was by strapping, heat and cold, massage, and sometimes a Whitman brace.

A Self-Retaining Trocar and Cannula for the Aseptic Evacuation of Distended Viscera.—Dr. Howard Lilienthal said that in cases of intestinal obstruction in which it became necessary to puncture the intestine, there was great danger from infection, because the puncture could not be made aseptically. Dr. Lilienthal experimented with a long piece of dead gut, connecting one end with a faucet, and tying a string about the other, so distending it with running water. With the instrument he presented he made his first puncture in this dead thin atonic intestine and it worked perfectly. Then he experimented on the living subject, with perfect results. He punctured an empyema of the gall-bladder, evacuating twelve ounces of pus in a few minutes, without any leakage. Then there was the crucial test made in a case of chronic intestinal obstruction, with acute symptoms. There was an enormously distended gut filled with fluid feces; two punctures were made and nearly a gallon of fluid feces was evacuated without soiling the peritoneum.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 11, 1906.

Dr. Matthias Nicholl, Jr., *in the Chair.*

Demonstration of an Improved Croup Kettle.—Dr. Theron W. Kilmer presented this croup kettle for the administration of hot moist air, and also an apparatus for the application of hot dry air.

A Case of Enlarged Spleen in a Child with Marked Anemia.—Dr. Eli Long presented a girl, three years old, whose family history was negative. She had always been very white. The abdomen had been enlarged for at least two years. The many blood examinations made were practically all alike. The red cells numbered 1,840,000, the hemoglobin amounted to from 20 to 30 per cent., the leucocytes were from 12,000 to 15,000, and there were many variations as to size. Poikilocytosis was very marked. There was nothing abnormal in the stools or urine, but there was a starchy indigestion, probably due to overfeeding. Many diagnoses had been made by different men. One said it was a case of primary progressive pernicious anemia, but the history of the case, running over a period of two years at least, and with improvement since being under treatment, negatived this diagnosis. This disease, too, was rare in children. Dr. Rotch of Boston could find no instance of it. The spleen was very large, the liver moderately so. No indications of intestinal toxemia were elicited. The results of *x*-ray treatment were not encouraging. There was no temperature and the bowels moved daily. Iron, cod-liver oil, and oxygen had been given.

Dr. Thomas S. Southworth said that the case looked like one of von Jaksch's pseudoleukemia, rather than one of pernicious anemia. The child had a distinctly yellowish color of the skin which was peculiar to pernicious anemia. The earlier writers on leukemia called attention to the pale yellow color in these cases. There were rickety stigmata of the head and chest, with an enormous spleen, and the liver was, in his opinion, larger than the one outlined by Dr. Long. The leucocytosis was not as high as von Jaksch originally reported. A relatively high degree of leucocytosis was not necessary to pseudoleukemia. A case he had seen improved markedly before lost sight of under the administration of phosphorus and cod-liver oil.

Dr. Charles Hermann said it was a singular thing to find this condition among the Jewish and Italian children, especially in the case of twins, and Hutchison had attempted to explain this by stating that the iron which the infants needed was not sufficient in amount to go around. In these cases he thought there must be some other factor than syphilis or rickets to give rise to this disease, probably some congenital anomaly in the blood-forming organs. He believed the child would die of some intercurrent disease, as measles or bronchopneumonia. The prognosis was not bad *per se* but from intercurrent diseases. Bone marrow had been tried in Europe with good effects.

Dr. Long said that bone marrow had been given the child since it had been in the hospital.

A Case of Hypertrophic Stenosis.—Drs. John Howland and John Rogers reported this case. The patient, a baby, was first seen on May 4, 1905, in consultation with Dr. Rogers when he was five weeks old. He was then the youngest of three, the other two being strong and well nursed by the mother for ten months each. He was a large baby, weighing nine pounds and seven ounces at birth. He began to nurse on the first day and did very well thereafter for three weeks, weighing at the end of this time ten pounds and four ounces. During these first three weeks there had been very little vomiting. After this time, however, he began to do badly, the prominent symptom being vomiting. This was excessive and persistent and forcible. It occurred after each feeding, sometimes immediately after, and sometimes it was delayed an hour or more. He was very hungry, but the more he nursed the more he vomited. The vomiting was projectile. He took some water and kept it down, but he seemed to have pain and cried sharply. At first his stools were fairly normal, but later he developed great constipation. For the next three weeks various measures were tried, to all of which he would respond for a time, and after the old symptoms would return in full force. Thus when barley water and bicarbonate of soda were given before his nursings, and the interval between them made three hours, his vomiting diminished greatly in amount. The same was true when one grain of sodium salicylate was given after his nursing, but all of this time he lost weight and when eight weeks old weighed but 8 pounds and 3 ounces, 2 pounds and 1 ounce below his top weight. An occasional feeding of modified milk was tried but he would not retain the smallest quantity of this. Stomach washings were tried and were successful for a time, but the vomiting returned again as markedly as ever. The mother's milk failed and he was given prepared food very dilute. The vomiting all this time was very frequent but not after every feeding. Sometimes he would go twenty-four hours or more but the stomach contents could be found with the tube eight hours or more after feeding. His constipation was obstinate. He was hungry and would suck at the bottle eagerly for a

minute or two and then cry with pain, draw up his legs, and could not be induced to take more. At this time peristaltic waves could be plainly seen beginning just below the free border of the ribs on the left side and traveling slowly across the epigastrium to just beyond the median line where they faded away and others succeeded them. They would come on for one-half hour or more. The stomach was slightly dilated, extending just to the umbilicus. Although for some time there had been no doubt as to the condition present they were loath to submit the child to so serious an operation as a gastroenterostomy, were there a chance for him to recover without it. His improvement after each new therapeutic measure held out hopes for a time but finally when he was three months old, weighing 7 pounds and 4 ounces, three pounds less than his top weight and 2½ pounds less than his birth weight, he vomited every drop he took and it was seen that there could be no further delay. The operation was performed by Dr. John Rogers. The subsequent history could be passed over rapidly. Water in half teaspoonful doses was begun eight hours after the operation and the amount gradually increased. He did remarkedly well when milk was added, and in a few weeks he was on a mixture proper for a child of his development. He gained flesh rapidly and his digestion had been perfect. Last month he had an attack of bronchitis and vomited once with this but made a rapid recovery.

Dr. Rogers classified the operations for pyloric stenosis as pyloroplasty, gastroenterostomy, divulsion of the pylorus, and pylorectomy. In Dr. Howland's case pyloroplasty was impossible and pylorectomy he considered a difficult operation at the best. In this case he did not see how divulsion of the pylorus could be done and gastroenterostomy seemed to him to be the only feasible operation, performing it without the loop. The operation was quite simple because there were no adhesions and no fat to be encountered.

Dr. Herman Schwarz asked regarding the chemical examination of the stomach contents.

Dr. Howland replied that free hydrochloric acid was found.

Dr. L. E. LeFetra said it was a great privilege to be present at the reporting of the first successful case of this kind in a patient so young, and he congratulated them upon the brilliant results obtained.

Dr. Matthias Nicoll, Jr., asked Dr. Rogers what the exact prognosis was after each of the operative procedures he mentioned.

Dr. John Rogers replied that in gastroenterostomy by suture, the prognosis was 62 per cent. with 16 cases; with the button, 100 per cent.; pylorectomy, gave a mortality of 100 per cent; pyloroplasty in 6 cases gave 50 per cent., while divulsion with 8 cases gave a mortality of 25 per cent. The average mortality was about 73 per cent.

Congenital Stridor of the Larynx.—Dr. Elisha Mather Sill presented a baby 9 weeks old with this congenital stridor, a very rare condition and first described by Thompson. It was characterized by a noisy sound, especially on inspiration, more like a grunting sound. It was supposed to be due to spasm of muscles, choreiform in character. Some claimed it to be due to an enlarged thymus. Again some claimed it to be due to abductor paralysis of the laryngeal muscles causing a falling in of the walls of the larynx during inspiration. There was practically no treatment for the affection, most children getting well as a rule.

Dr. Herman Schwarz said that he had seen three cases recently, in two of whom the *x*-ray showed an enlarged thymus.

Dr. Southworth referred to the case recently reported by Dr. Koplik in which there was a rolling up of the epiglottis.

Dr. Sill replied that the bronchoscope had been used and no such rolling up of the epiglottis had been noted.

Dr. Charles G. Kerley said that clinically there were differences between cases of the kind presented and those with enlargement of the thymus which came under observation, especially at autopsy. In one of his patients with enlarged thymus who died during an attack of laryngismus, there had been repeated attacks of stridor with apnea, complete loss of breath and a period of unconsciousness. He had seen as many as eight cases, six coming to autopsy. One case had thirty attacks prior to death. In the intervals there was no stridor or crowing sounds whatever. He thought these cases were due to what Dr. Sill had described as "sinking in" following abductor paralysis rather than any special nervous influence. If nervous influences were present these spasmodic attacks would be worse at times.

Dr. L. E. LaFetra said he never saw a child with this condition who was over the age of one year, and believed these cases were more common than generally supposed. There was a great difference between laryngismus stridulus and congential stridor.

Dr. Kerley recalled a case in a child of 16 months.

The Diagnosis and Treatment of Chronic Polyarticular Disease in Children.—Dr. P. Wm. Nathan read this paper. Among chronic polyarticular diseases he included all those joint affections with multiple lesions, which showed a marked tendency to produce permanent joint impairment. These were the joint diseases which had usually been classed under the various heads of chronic rheumatism, rheumatoid arthritis and arthritis deformans. After detailing the histories of a number of cases, typical of certain joint diseases, and showing how these various forms might be distinguished from each other and how, by so differentiating them, they were in a position to treat them more rationally and satisfactorily, he said that infectious osteoarthritis could be differentiated from primary infectious arthritis by the early bone swelling, by the fact that the effusion and joint spasm subsided when the joint was placed at rest, though the bone swelling still persisted. In the early stages pain was elicited by pressure over the bone focus and later the deformation was found to be entirely due to bone destruction. From this it was evident that the deformation and joint disability was apt to be much more serious and permanent in osteoarthritis than in primary arthritis. It should be remembered, however, that one might have an epiphyseal bone inflammation which, under favorable conditions, might never directly penetrate into the joint proper, *i.e.* one which remained an ostitis and never became an osteoarthritis. He said that any of the infective microorganisms might cause chronic non-suppurative joint inflammation and the character of the disease seemed to depend upon the number and virulence of the invading organisms or their location either in the bone or in the synovial membrane than upon the variety of the infecting organism. There was one exception to this rule and this seemed to be the gonococcus. The latter showed a marked tendency to invade the periarticular structures causing an intense infiltration. This was the cause of excruciating pain in this form of joint disease. The pain in gonorrhoeal arthritis and osteoarthritis was so intense and so much greater than that of other forms of infection that it had been of service as a diagnostic factor. In the earlier stages of non-suppurative polyarticular disease it was often impossible to say definitely whether the case was one of primary arthritis or osteoarthritis. Fortunately the treatment in the earlier stages was exactly the same in both forms, so that a differential diagnosis was not absolutely necessary at this time. The fundamental principle of the treatment in the earliest stages of all joint disease was perfect rest for all the joints involved. The readiest means of keeping the joints quiet, absolute immobilization, was the plaster of Paris bandage. In osteoarthritis the pain entirely disappeared in a large percentage of the cases as soon as the bandage had been

applied. The joints should be kept immobilized until all constitutional symptoms and all signs of active inflammation had disappeared. It was important to differentiate between osteoarthritis and arthritis. In the septic form this did not present any difficulty. Aside from the syphilitic and tuberculous osteoarthritis, the typhoidal and pneumococcal were the most important infectious joint diseases, which presented both osseous and synovial forms. On removing the immobilizing apparatus the joint swelling disappeared, but one could nearly always detect a certain amount of bone swelling in the region of the joint. In the gonorrheal form he had not infrequently found bone swelling in the various parts of the shafts of the bones. In the osseous forms the infection might take the form of a focus and spread in all directions from this or the epiphysis of the bone might become more or less rapidly and diffusely infiltrated. In both forms there seemed to be rapid bone absorption. When the disease was undergoing resolution there was always a tendency to hyperplastic bone processes which resulted in overgrowth. If the disease penetrated to the cartilage, causing its destruction, the tendency was to bony and ankylosis. Because of the tendency to deformation the active use of the affected part should be delayed until the bones had resumed their normal density. If the bones were immobilized too long, there was great danger of bone overgrowth and ankylosis. The affected joints should be freed from plaster-of-Paris bandages and placed in suitable splints as soon as the very acute symptoms had subsided. Gentle passive motion should then be inaugurated. The treatment of the synovial forms when the acute and subacute symptoms had subsided was important. Prolonged immobilization was not here alone permissible but distinctly advantageous. When the bandages were finally removed it would be found that the joints were quite stiff, but by gentle passive motion they would give a little. A little more force was permissible than in the osseous form, but great care should be exercised not too employ too great force. The time at which these patients should be allowed to use their joints was not always easily settled. If allowed to use them too soon the joints became swollen and painful and permanent joint damage should be guarded against. The use of splints and passive motion he continued for a long time, depending more or less upon the severity of the initial attack. Recurrences are treated like the initial attack.

Some Fat Problems and Goat's Milk in Infant Feeding.—Dr. J. Finlay Bell of Englewood, N. J., read this paper. He said that since the earliest days of milk modification the disproportion of lactalbumin to caseinogen and the physical and chemical differences of the latter in cow's when compared with human milk had been the one apparently insurmountable obstacle in the way of adapting the cow's milk to the infantile dietetic. The question had long been in his mind as to whether there was not a great variation in the fat constituents of the various milks quite as diverse and important as the variations in proteids. In May and June, 1905, while engaged in comparative fat estimations, he had found that goat's milk fat remained fluid while cow's milk fat became solid after cooling. If permitted to stand for twenty-four hours or longer, the goat's milk could be poured out without the aid of heat, but the fat of the cow's milk required heat. He cited two cases in which goat's milk properly diluted had been used with success when the infant tolerated no other food in the way of milk. An analysis of human, cow's and goat's milk had thus far shown that both goat's and human milk fat contained much less stearin than that of cow's milk fat, and that goat's milk fat contained more olein than that of cow's milk fat and more than the particular sample of human milk used in this analysis. Pavlov and Labassoff in their experiment on dogs found that the gastric secretion curve was very different when a fat was given from what it was when substances free from fat were administered. Their experiments seem to show that fat inhibits the normal energy of the secretory process, either by hindering the secretion in a mechanical way or by covering the mucous membrane of the stomach and preventing excitation of the nerve endings or else indirectly by reflexly stimulating the inhibitory nerves of the glands or the inhibitory centers of those nerves. Dr. Pavlov stated that the action of fat might possibly explain the slow progress of secretion after taking milk and also the low digestive power of the juice, and questioned whether the fat of the milk might not be credited with this. He had also shown that the ingestion of fats increased the flow of pancreatic juice and probably a flow that was richer in steapsin. These experiments were carried on with milk, using the same sample by first depriving it of its fat and again adding it and collecting separately the juice through a pancreatic fistula. An average of 10 analyses of goat's milk from one goat gave an average of fat percentage of 4.8 per cent., proteids 3.8 per cent. (proteids not split). The sugar was not estimated. Two bacteria counts gave 10,000 and 12,860 per c.c. A few of the colonies were examined microscopically and were found to be made up mostly of round bacteria in the form of staphylococci and streptococci. Samples of goat's milk and cow's milk taken at the same time were placed side by side on a shelf, and at the end of five hours the cow's milk had soured, but the goat's milk did not sour until the end of eight hours. In curdling the milk with rennet the curd of the goat's milk seemed harder and more fibrinous than that of the cow's milk. The whey of goat's milk, when subjected to the Woodruff test for albumin, showed a percentage of 1 per cent., while that of the cow showed 92 per cent. The reaction of goat's milk was found to be slightly acid to phenolpthalein. The average specific gravity was 1,032. A comparison of melting points of milk fats from goat's and cow's milk showed that for cow's milk this point was from two to three per cent. higher than for goat's milk. He said that it seemed probable that a great deal of mystery heretofore existing in the adaptation of milk to infant feeding, not only as regarded fat, but proteid indigestion, would be largely cleared up by a more intimate knowledge of the chemistry of the fat constituents employed. He believed that good milch goats would give a larger milk ratio per expense of food and keeping than cows. The goat was more docile, less excitable, and not subject to tuberculosis or other diseases of this climate. The goat would thrive where the cow would not, and above all was cleanly. The production of cow's milk free from manure bacteria was practically impossible, commercially, but this was not true of goat's milk. He concluded that the digestion of fat retarded the flow and diminished the amount of gastric juice, at the same time lowering its digestive power, and that the ingestion of fluid oil increased the flow of pancreatic juice and probably the activity of its fat-splitting steapsin. In case the fat was not fluid at body temperature it might still further retard and prevent the flow of gastric juice. The fat might coat over the curds, thereby preventing the action of the gastric juice upon them. It might also prevent the action of trypsin upon them though brought in contact with an increased supply of pancreatic juice. He thought that goat's milk merited thorough and extensive clinical trial in infant feeding.

Dr. Joseph E. Winters said he had seen a number of cases in which babies were fed on goat's milk with very satisfactory results.

Dr. Matthias Nicoll, Jr., said that he did not believe that commerically goat's milk would ever supplant cow's, but he believed that there should be some provision made by which goat's milk could be supplied, especially in the large cities. Italians on the east side, when their babies were apparently hopelessly ill, fed them with goat's milk and with remarkable success.

College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting held March 12, Dr. David Riesman reported "A Case of Scleroderma." The patient was a woman some fifty years old, who presented swelling, rigidity, and impaired mobility of the skin of the hands and feet in varying degree, together with symptoms of local snycope. Drs. Wm. G. Spiller and J. C. Gittings read a paper entitled "Cervical Rib Associated with Cervicobulbar Palsy." The conditions were present in a young man, nineteen years old, who had a cervical rib on either side, and weakness and wasting of the muscles of the face and upper extremities, in the absence of exaggerated reflexes. Both disorders must be looked upon as the expression of an anomaly in development. The association is an exceedingly rare one. Dr. Robert N. Willson presented a communication entitled "Mercurial Nephritis, with the Report of a Fatal Case." The patient was a man who had been treated successfully for pericarditis, and who was given one grain of calomel every hour for twenty-four doses. Symptoms of nephritis developed and proceeded to a fatal termination. After death the lesions of chronic nephritis were found. Dr. M. Howard Fussell reported "Two Cases of Aneurysm of the Aorta." One patient exhibited edema of the upper extremities, with lividity, and after death an aneurysm of the arch of the aorta communicating with the descending vena cava was found. Dr. J. Alison Scott reported "A Case of Aneurysm of the Descending Thoracic Aorta." The patient was a woman presenting a pulsating tumor in the back below the angle of the left scapula. Into this twenty feet of gold wire was introduced and a galvanic current passed. Rupture, however, ensued eventually. Drs. A. O. J. Kelly and Ralph S. Lavenson reported "A Case of Aneurysm of the Aorta."

New Instruments.

IMPROVED VACUUM ELECTRODE FOR CATAPHORESIS.*

By JOHN C. LESTER, M.D.,

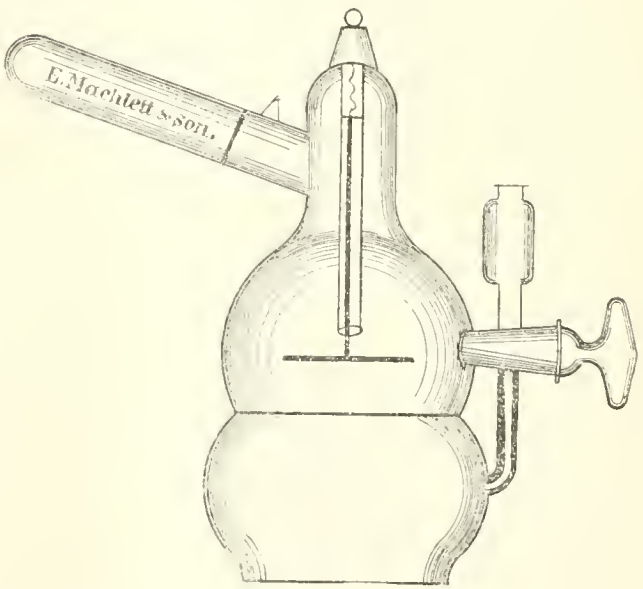
NEW YORK.

About a year ago in an article read before the American Ophthalmological Society I took occasion to report the treatment of several cases of intraocular conditions treated by the so-called high-frequency current. The cases then reported as cured have remained so, and the cases then under treatment have continued to improve; in fact, are now practically well. Recently cases of another description have come under my observation and care—cases in which the fifth nerve was especially involved, more particularly cases of supra-orbital neuralgia. Ordinary vacuum electrodes used in other forms of treatment were employed, as well as the one devised by Dr. Morton, with more or less success. After using these electrodes it occurred to me that an adaptation of the old cupping-glass principle combined with the vacuum electrode, as ordinarily used, could not help increasing the therapeutic value of both. After having combined these two principles in the form of one electrode, it occurred to the writer that a valuable addition might be made to the cupping-glass by the addition of a capillary tube and stop-cock to the distil end of which was also attached a small vial or receptacle for the introduction of various medicinal agents. E. Machlett & Son, of New York City, from suggestions and drawings by the writer, have perfected this electrode.

The illustration given herein perhaps conveys a better idea of the electrode as compared than any written description could do. They are made in three sizes and in two different styles. In experimenting with these electrodes, I have found that although they work with high-frequency currents obtained from both the static machine and the induction coil, certain shapes or forms and depths of the cupping-glass are better adapted to the current obtained from the static machine, and other forms and depths of the cupping-glass are better adapted to the high-frequency current obtained from the coil.

Perhaps, in this connection, it might not be out of place to suggest the right method of employing this electrode. The electrode should be attached to the coil or static machine in the usual way. In order to use the cupping-glass successfully in the average case and without giving too much pain on application, I have found the best method of producing a vacuum in the cupping-glass to be as follows:

A cotton tipped applicator is saturated with ninety-five per cent alcohol. This is lighted with an ordinary alcohol lamp and immediately introduced into the cupping-glass attachment and repeatedly swept around the inside of the cupping-glass. In this manner sufficient alcohol is thrown off on the inside of the glass to continue burning



until the electrode can be pressed upon the part to be treated. If this is done quickly and in the method described, there will be no burning of the tissue and practically no personal discomfort to the patient. After the electrode has been attached this way, any medication desirable can be introduced through the tube by turning the stop-cock and allowing it to flow down from a receptacle at the top which, of course, has been previously filled and a rubber cork introduced to prevent its running out. In the manner described I have employed such drugs as iodine, cocaine, holocaine, and solutions of menthol, with more than satisfactory results.

I would also state, in this connection, that any base can be used, but preferably such bases as are most frequently used for cataphoresis: in other words, those bases which experience has shown are most easily introduced through the skin.

Drs. John F. McParland and Wm. Bedford Brown, of this city, have employed this electrode in several cases, Dr. McParland especially in

*Annual meeting held at Boston, Mass., May, 1905, and published in the report of the Ophthalmological Society.

diseases of the chest, and he reports to the writer that he has had more than satisfactory results in these cases. Dr. Brown has also employed this electrode in various skin diseases and reports equally good results.

My own experiments thus far have been connected with certain pathological conditions of the eye, ear, throat and nose.

These experiments and any definite results obtained will be reported later on.

A twelve-inch coil in connection with a Besser interrupter has been used.

The Besser electrolytic interrupter has proven especially valuable, owing to its small resistance, evenness of interruption and, more particularly, the possibility of continuous use without variation or loss of efficiency—qualities, which will surely appeal to any one who has had extended experiences with many of the interrupters now in use.

616 Madison Avenue.

A PHONENDOSCOPE ATTACHMENT.

By M. D. BLOOMFIELD, M.D.,

NEW YORK.

I beg to offer to the profession this little device of mine which combines a bell stethoscope with a phonendoscope, thereby increasing the sound over the ordinary bell stethoscopes. Its advantages are obvious. Though the increase in the sound is hardly more than that heard by the ordinary phonendo-

scope, the latter is not practical in searching for very fine sounds. The bell covering a smaller area excludes a multiplicity of sounds, thereby selecting the focus desired, and when an intensification of the sound is desirable, instead of the physician carrying two instruments in his pocket, by this plug arrangement a very convenient and portable stethoscope and phonendoscope is combined into one piece.

Montefiore Home.

Vaccination Made Easy. — The Mayor of Madrid, in order to encourage vaccination, has established a lottery, a ticket for which he presents to every one who submits to the operation.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cas and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending April 28, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	475	175
Diphtheria	337	40
Measles	1454	39
Scarlet Fever	237	13
Smallpox	2	1

THE ETIOLOGY OF ACUTE RHEUMATISM.*

BY LEWIS FOX FRISSELL, A.M. M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE SETON HOSPITAL.

THE idea that the disease known as rheumatic fever or acute articular rheumatism is of bacterial origin is no new one; in fact, the suggestion dates well back toward the time when the bacterial origin of any disease was still disputed. As early as 1888 Birch Hirschfeld,[1] arguing from the similarity of rheumatism to the other forms of bacterial invasion, suggested that this, too, might be due to a bacterium as yet undiscovered. Following this suggestion, efforts to isolate the organism have been made during the past two decades. Sahli[2] in 1892 announced that he had isolated from all the serous membranes of a fatal case of rheumatism the staphylococcus citreus. Though of the opinion that he had isolated an organism causing a disease the clinical picture of which was typical of acute articular rheumatism, he leaves the question open as to whether his coccus is specific or an attenuated pus producer. Following the same line of thought in a discussion on the relation of endocarditis to rheumatism, v. Leyden[3] announced that from old cardiac vegetations he had isolated in six cases a diplococcus which he thought might have a causal relationship to the disease. Animal experimentation, however, was without result.

This field of investigation now began to attract the attention of French bacteriologists. Achalme[4] in 1891, and again in 1897, isolated from the heart blood of a fatal case of rheumatism a large bacillus. Later he again found his organism in four cases, but only twice in pure culture, the other two showing cocci as well. The general appearance of his bacillus is that of the organism of anthrax. Culturally there is nothing characteristic except the fact of its being an anaerobe. Though often fatal to animals, neither cardiac nor arthritic lesions were produced. These results were shortly afterward confirmed by Thiroloix. Triboulet[5] in 1898 found a diplococcus in eleven rheumatic cases, his results being shortly afterward confirmed by Coyon[6] and Apert.[7] Injection of cultures into guinea-pigs killed the animals in about twenty days, with autopsy findings such as pericarditis, valvular lesions, pleurisies, but no case of arthritis. Pus was in no case produced. The organism was readily recovered from the blood.

In Germany at about the same time Wassermann[8] isolated from a case of rheumatism, complicated by chorea and endocarditis, a diplococcus. This organism was obtained from the blood, the brain, and the cardiac valves. Alkaline media were essential to its best growth, on others the growth being very scant. Animals injected after an incubation period of three to ten days developed periarthritis without pus formation. As the first experimenter to produce joint symptoms in animals, Wassermann concludes that his organism is specific. Apropos of his statement that very alkaline media are most favorable to the growth of the diplococcus, one is led to think of the possibility of doing harm by the common alkaline treatment of the disease.

One of the most elaborate researches and one of the most successful was carried out by Poynton and Payne.[9] Beginning their work with the idea of finding Achalme's bacillus, and unsuccessful in this endeavor, they isolated in eight cases a diplococcus, three times from the blood of rheumatic cases in life, once from the throat, and the remainder at autopsy. Morphologically the diplococci resembled the organism isolated by Triboulet and Wassermann, but culturally the Englishmen found a medium of milk and bouillon slightly acidified with lactic acid the best. Though facultative aerobes, their best growth occurs under anaerobic conditions. Animals inoculated developed, after an incubation period of a few days, symptoms of a polyarthritis, the different joints being successively attacked. Pyrexia, rapid heart action, and murmurs were other symptoms. At autopsy the joint fluid was usually clear, sometimes a little turbid, but never contained pus. The heart was frequently affected, both endo- and pericardical lesions being found. Other occasional findings were pleurisy, pneumonia, fatty degeneration of the myocardium, coagulation necrosis of the liver, spleen, and kidneys. The diplococci could be readily recovered from the blood and joints, and were demonstrable in sections of the cardiac valves and articular tissues. Continuing this line of research in a later paper, their previous results were confirmed, bringing to sixteen the total number of cases from which their diplococcus had been isolated. Particularly interesting is the case reported in which a rheumatic nodule was excised, under aseptic precautions, from the subcutaneous tissues, and planted *in toto* in the author's milk and bouillon medium. Growths of diplococci obtained from this produced the typical symptoms in rabbits, sections of whose joints showed this organism. Also of special interest is the fact that in one rabbit distinct choreiform movements were produced. Naturally Poynton and Payne[10] conclude that their diplococcus is specific, basing their opinions on the uniformity of the symptomatology and on autopsy findings in their animal experimentation.

Fritz Meyer,[11] after failing to obtain a growth from blood and joint cultures, isolated a diplococcus from twenty-five cases of rheumatic tonsilitis by the ingenious method of injecting a mixed throat culture into the ear vein of rabbits, and, in event of producing arthritic symptoms, obtaining the organism in pure culture from the joints. In its appearance and reactions it does not differ from the organisms isolated by Triboulet, Wassermann, and Poynton, and Payne, but a medium containing peptone and ascites fluid was found best by this investigator. The growth in anaerobic cultures retained its viru-

*Read before the Presbyterian Hospital Alumni Association, December 9, 1905.

lence much longer than aerobically. This diplococcus may be distinguished from the ordinary streptococcus by (1) its greater hemolytic action; (2) the difficulty in changing its virulence by passing it through a series of animals; (3) its free growth in a nitrate of streptococci of human origin in which ordinary streptococci will not grow. In a series of a hundred rabbits inoculated, he in every case produced the symptoms of a polyarthritis after an average incubation period of six to eight days. The joint fluid was serous, rich in mononuclear leucocytes, but never contained pus. Diplococci could be both demonstrated in the joint fluid and grown in culture media if obtained during the first few days of the effusion, but later the fluid was sterile, thus resembling the findings in man. In 21 per cent. of his rabbits an endocarditis was produced, a percentage which closely approximates that of human rheumatic cases which develop endocardial trouble. To prove the special affinity of his organism for serous membranes, mixed cultures of the diplococcus and pyogenic staphylococci were injected into animals, with the result that after a short time while the staphylococci could be readily recovered from the blood, the diplococci could only be obtained from the joints, where, on the contrary, no staphylococci were found. Beaton and Walker[12] in 1903 confirmed the results of Poynton and Payne by isolating from fifteen cases of rheumatism, endocarditis, or chorea, the diplococcus, usually from the heart blood post mortem, but on several occasions also from the urine. In their animal experimentation large doses caused death in forty-eight hours with pericarditis and vegetations on the cardiac valves. Moderately large doses were fatal in from three days to three weeks, with effusion into the joints; while small doses in from three to six days uniformly caused a polyarthritis, which showed a disposition to spontaneous cure; in a few cases pus was found. In cultural characteristics the organism resembled that isolated by their predecessors. A few months later the latter of these two investigators, in collaboration with Ryffel,[13] made a study of the chemical products of the micrococcus of rheumatism. A considerable quantity of formic acid was formed by the growth of the organism, both in the bodies of the cocci and in the filtrate of the media in which they were grown. Streptococci, on the contrary, produced very little formic acid. Now an interesting clinical fact is that in the urine formic acid is not a normal constituent, but it is present in the urine of rheumatics, where it is reduced in amount by the administration of salicylic acid. Formic acid is also found in the tissues of rabbits which have been injected with the micrococcus of rheumatism. Of interest in this connection is the old tradition that beekeepers who are subjected to the stings of their charges are relatively free from rheumatism. The most recent contribution to the literature was published last fall by Lewis and Longcope.[14] These gentlemen isolated during life from the blood of a rheumatic with both endocarditis and chorea a delicate diplococcus. They also succeeded in producing a polyarthritis in rabbits and recovering the organism from the joints.

So much for positive results. Menzer,[15] as a result of his extended work with cocci, has reached the conclusion that many forms of disease, among them rheumatism, are caused by cocci, influenced principally by two factors—the general or local resistance of the body, and the attenuation or virulence of the coccus in question. Such diseases as rheumatism, scarlet fever, pyemia, and measles he considers as thus caused.

Singer,[16] in a monograph published in 1898, insists that, while rheumatism is undoubtedly of an infectious nature and caused by bacteria, these bacteria are the ordinary pus producing cocci, possibly of weakened virulence. The bacteria were obtained at autopsy, though it may be noted that he reports in many cases the large white staphylococcus, which in this country we have come to regard as a skin contamination.

Hoping to confirm the observations already made, a number of experiments on animals were made during the past winter in the laboratory of the Presbyterian Hospital, the clinical material being furnished by cases in the wards and a few seen in private. First an effort was made to isolate an organism from the joint fluid of rheumatic cases. In these experiments the following routine was employed. The joint was aspirated under aseptic precautions as soon as possible after the first appearance of the fluid in the joint cavity; usually within twenty-four, and always within seventy-two hours. Cultures were then made both in bouillon and on blood serum, and often in ascites bouillon and milk and bouillon media. Seven joints in all were aspirated. The fluid obtained varied in its degree of turbidity and leucocyte contents, but never showed in smears distinct bacteria, though in one or two, suspicious coccus-like bodies were observed. Cultures on bouillon and blood serum were made in four cases. Three were entirely sterile, while in the fourth a spore forming bacillus was obtained in one tube which was without effect in producing arthritic or cardiac lesions in animals. It was therefore considered a contamination. The joint fluid from four cases was injected directly into the ear veins of rabbits without producing an appreciable effect.

Three cases of erythema nodosum were seen. In these a blister was raised on the node, the skin of which had previously been rendered aseptic, and cultures were made on serum and bouillon tubes. From one case the culture medium remained sterile, while in the other two white staphylococci were isolated, probably skin contaminations. Injections of fresh cultures into the circulatory system of rabbits were without result.

Failing to obtain from joints or nodes an organism which seemed likely to have a casual relationship to rheumatism, the tonsil as the probable portal of entry was next investigated. Following the method of Meyer, cultures were made from those cases of tonsillitis occurring in the course of an attack of acute articular rheumatism, or from such cases as from the personal history or clinical symptoms seemed likely to be of a rheumatic nature. The cultures were of course a mixed growth, but the streptococcus was nearly always the predominating organism and this often in almost pure culture. A young twenty-four hour bouillon culture of this organism, usually to the amount of five c.c., was injected into the ear vein of a rabbit. At this point it may be well to say that according to our observations the normal temperature of rabbits is extremely variable, running anywhere from 101° to 104° F., so that notwithstanding statements of other observers who mention among the symptoms produced a pyrexia with a temperature of 102° to 104° this seems to us no very reliable indication of disease. Six rabbits showed no symptoms whatever, except in some instances a slight indisposition immediately following the injection. One died within twenty-four hours without demonstrable lesion on autopsy, an effort to recover the organism from the heart blood being unsuccessful; the second died within three weeks without symptoms of arthritis but with a peritonitis

and slight pleurisy. Cultures from the heart blood gave a coccus like the pneumococcus; those from the pleura and lung were contaminated by a putrefactive organism. The coccus isolated caused the death of another rabbit in twenty-four hours, but no lesions were demonstrable on autopsy. The organism was again recovered and determined to be the pneumococcus. The third developed an abscess of the ear six days after injection, and in ten days an arthritis of the left knee. Aspiration of the latter showed it to contain pure blood, but no growth could be obtained either from the joint fluid or from the pus of the ear. Some months later, after all symptoms had cleared up, this rabbit died, the autopsy showing no lesions either of joint or heart.

Not until the end of the winter of 1904 was a bacterium isolated which produced a constant train of symptoms in animals. The results were so remarkable that it seems worth while to report rather fully the clinical course of the patient from whose throat the original cultures were obtained. On March 15, S. S., an alcoholic woman, fifty-four years of age, was admitted to the ward of the Presbyterian Hospital. She had suffered from rheumatism at intervals for eleven years. Ankles, knees, and hips had all been affected. The joints of her fingers were deformed, but she seldom had had sore throat or rheumatic nodes. Physical examination of the heart showed a mitral stenosis. She was admitted to the hospital after a hard drinking bout, nervous, with headache, vomiting, a puffy face, but with no joint symptoms; in other words suffering from alcoholism and a slight nephritis. Four days after admission she complained of pain in the right knee and shoulder, as well as in both arms and hands. Her temperature, which had been running irregularly between 100° and 101°, suddenly shot up to 104°.

Examination revealed a marked swelling of the right knee which was distended with fluid, but not reddened. The throat showed diffuse reddening of the tonsils and pillars of the fauces, but no exudate. The knee was aspirated under aseptic precautions and twelve c.c. of a turbid fluid withdrawn. No growth was obtained either on blood serum, in bouillon, or Poynton and Payne's milk and bouillon medium. Five c.c. of the fluid were injected directly into the ear vein of a rabbit without other result than a temporary prostration. The illness of the patient in question subsequently ran an uneventful course after involvement of several joints, and she was discharged from the hospital some weeks later much improved.

The throat culture made on Loeffler's blood serum showed, as usual, a mixed culture containing (1) Fine watery colonies, which microscopically proved to be cocci with a disposition to arrange themselves in chains; (2) the staphylococcus pyrogenes aureus. Transplants of the former to bouillon showed them to be cocci arranged in chains both long and short, apparently differing in no respect from ordinary streptococci. Four c.c. of a twenty-four hour culture of this organism were injected into the ear vein of rabbit No. 1. In four days, after some questionable temperature elevation, the rabbit seemed sick. Four days later, after a total incubation period of eight days, he appeared very lame in both forelegs, which, on examination, showed distinct swelling of both carpal joints. Two days later, ten after injection, the rabbit was killed, the autopsy showing the following condition: The pericardial sac was distended with a clear fluid, while in the neighborhood of the great vessels was a little deposit of fresh fibrin. The endocardium was smooth, as were the valves, with no evidence of fresh lesions, though around both mitral and tricuspid valves a cartilaginous ring was found. The carpal joints were filled with a thick, whitish, viscid fluid having the appearance of muco-pus. Stained smears of this fluid showed the presence of a large number of eosinophile and neutrophile polynuclear cells. No degeneration of the leucocytes was evident. No bacteria were found. Pus was present nowhere else in the body. Cultures were made from the pericardium, heart blood, and joints, the media used being bouillon, blood serum, and milk and bouillon. In one bouillon tube from the pericardium a growth was obtained, the other tubes remaining sterile. This growth in fluid media had the form of a diplococcus, but injection into a rabbit was without result, and later it was proved to be the white staphylococcus. Of the joint cultures, two bouillon tubes remained sterile, while two showed a growth, the bouillon at the end of forty-eight hours being slightly turbid, and showing in the hanging drops a coccus arranged for the most part in short chains; pairs or clusters were also seen. Of the serum tubes one contained the white staphylococcus, the other was sterile. From the organism isolated in the bouillon tubes the rabbits of the series which we will next describe were inoculated, each receiving five c.c. of a twenty-four hour bouillon culture in the ear vein. The culture reactions of this coccus are not striking. Its growth is slow, in bouillon there is frequently but slight turbidity after forty-eight hours, while none of those characteristic clumps in a clear medium, so frequently seen in cultures of virulent streptococci, were present. After a long series of transplants the chains became much longer, while very many fewer pairs of cocci were seen. On agar the growth is very slow and fine; after about a week's growth the colonies hitherto colorless take on a faint whitish tinge. There is abundant growth, but no production of gas in the sugar media, *i.e.* lactose, glucose, maltose, and mannite. In Hiss' inulin medium coagulation does not occur. Litmus milk is acidified, but not coagulated.

Rabbit No. II.—This rabbit, the first of B series, received in his ear vein five c.c. of a twenty-four hour bouillon culture of the strain of cocci isolated from the joints of rabbit No. 1. After an incubation period of three days the animal showed some lameness of the left leg and slight swelling of the knee joint could be made out. Two days later the right carpus became involved. It was swollen and tender to pressure. During the next week the swelling in these two joints increased, and then gradually cleared up, until thirty-three days after inoculation the swelling had entirely disappeared and the rabbit appeared as well as ever. It was then injected with fifive c.c. more of a fresh culture from the same strain. Within twenty-four hours lameness and swelling of the right carpus were again apparent. These symptoms gradually cleared up, but the animal progressively emaciated, and seventeen days from the date of inoculation appeared paralyzed in all its extremities. Death occurring a few days later, an autopsy was performed which disclosed a large cheesy ovarian tumor. The heart and joints were found normal, nor was pus anywhere detected. Cultures from the heart blood were sterile.

Rabbit No. III was injected with five c.c. of the same strain. Two days after inoculation it was seen limping and showed distinct swelling of the right carpus. After slight improvement these joints became more painful and swollen. On May 12, a month after inoculation, the left tarsus became involved, and nine days later the other tarsal

joints, the other affected joints meanwhile remaining extremely swollen and painful. June 6, while the swelling of the tarsal joints was less marked, the carpus was evidently disintegrating, as distinct bony crepitus could be elicited. On June 9 the animal was killed and the viscera were found normal. The right carpus was filled with cheesy matter, and the bones showed distinct evidence of erosion. The tarsal joints were filled with a sticky, whitish, mucilaginous fluid. Cultures from the heart blood were sterile. Pus was not elsewhere present.

Rabbit No. IV, on April 22, received a similar dose from the same strain. Three days later he became very lame in the left hind leg, the tarsal joints of which were much swollen. On the fourth day the carpal joints of both forelegs and the other tarsus became involved, while the left tarsus was very tense. On April 27, its condition remaining the same, chloroform was administered and an autopsy performed. The joints were much distended and considerable periarticular edema existed. The joint fluid was the same thick, whitish, mucilaginous fluid which we had found in other cases. The pericardium and endocardium were normal. No pus was found elsewhere. Smears from the joint fluid showed a large number of polymorphonuclear leucocytes, both neutrophile and eosinphile, without evidence of degeneration. A few isolated cocci, for the most part in the form of diplococci, were seen. Cultures from the joints and heart blood remained sterile.

Rabbit No. V. The fourth animal to receive an injection of five c.c. from B strain became ill after an incubation period of two days. The right tarsus was the first joint involved. The following day it was lame in the left foreleg, without, however, showing any distinct articular swelling. On May 7, one day later, the right knee was distinctly swollen and tense. Autopsy on the same day showed the right knee distended with a thick red grumous fluid, without evidence of erosion of the articular surfaces. The right tarsus contained the thick mucilaginous fluid found in other cases of this series. The other viscera were normal, no pus being found elsewhere. Smears from the fluid showed the presence of many leucocytes as before, with, in addition, an abundance of red blood cells. A few cocci, intra- and extracellular, mostly in pairs, were also seen. Sections of the periarticular tissue showed the process to be inflammatory in nature, with many leucocytes throughout. A few cocci, mostly in pairs, were seen throughout the sections, both within the cell bodies and free. Cultures from heart and joints were sterile.

Rabbit No. VI likewise received the ordinary five c.c. dose of a twenty-four hour culture from strain B. Seven days later his gait was distinctly lame, the animal sparing his left hind leg. On the 18th, one day later, both tarsal joints were slightly swollen, this swelling growing more marked in the next twenty-four hours, at the end of which period the rabbit was killed. The tarsal joints were, as usual, filled with thick, mucilaginous fluid which contained, in addition, bits of cheesy matter. The liver contained numerous hard, white nodules of calcareous matter, along the course of the bile ducts. The consistency was hard, though some parts appeared cheesy. Sections showed degeneration of liver tissue surrounded by a dense connective tissue capsule. The nodules were apparently formed within the bile ducts. The inflammation was considered tuberculous. No pus was found here or in the other organs. The smears from the joint fluid showed the numerous leucocytes and many cocci, mostly in pairs. Sections from the periarticular tissue showed the presence of inflammation. The mesh of the synovium was distended and contained many leucocytes, as did the entire section. Many diplococci were seen throughout. Cultures were made from the heart blood and the joints, and a bit of periarticular tissue was excised under aseptic precautions and planted in bouillon. The tubes inoculated from the heart blood remained sterile. The bouillon tubes from the periarticular tissue and from the joints became cloudy after two days, and contained an abundant growth of cocci, in pairs and long chains. The cultural reactions of this organism were identical with those of the organism originally injected. Experiments on animals which follow conclusively prove that we had recovered the organism at fault.

Rabbit No. VII. This animal, instead of the ordinary inoculation in the ear vein, received five c.c. of a twenty-four hour fresh culture of B strain in the flank, subcutaneously. The injection was made with the idea of seeing whether our germ was an ordinary pus producer. Though carefully observed during a month's time, there was no appearance of abscess formation or even of local reaction. No joint symptoms followed.

Rabbit No. VIII received the customary injection into the ear vein. After seven days it appeared lame in both hind legs and the right foreleg. No swelling of the joints of the hind legs could be made out, but there was distinct, though slight, enlargement of the right carpus. Thirteen days after inoculation it was again perfectly well.

Rabbit No. IX. This animal received in the ear vein an injection of five c.c. of a forty-eight hour bouillon culture from the periarticular tissue of rabbit No. VI, and was therefore the first of the series to receive a pure culture already passed through one animal. After a short incubation period it became ill, fed badly, and in fourteen days from the date of inoculation died without showing any joint symptoms. At autopsy the pericardium was distended with a turbid fluid filled with fibrin flakes, with fresh masses of fibrin on both visceral and parietal layers. The endocardium showed on both mitral and tricuspid valves a few minute spots looking like fresh vegetations. Both visceral and parietal layers of the right pleura were covered with fresh fibrin. The lung showed a few patches of partial consolidation. On the left pleura were a few patches of fibrin. The left lung was normal. Cultures made from the pericardium and heart blood showed a few small diplococci, but were overgrown with small bacilli and a large coccus, both the latter probably post-mortem contaminations.

Rabbit No. X, on May 29, likewise received five c.c. of a fresh culture of C strain. In three days the right tarsus became swollen and painful, and a week later the other tarsal and right carpal joints became involved. Shortly afterward the rabbit passed from under our observation for two months. Its death occurred in September, when only the right tarsal joint was affected. This was distended and evidently disintegrated. Autopsy showed it to be filled with a sticky, mucilaginous fluid, smears of which showed the usual excess of leucocytes. The ends of the bones were eroded. The cocci were recovered but were contaminated by many other organisms of cocci and bacilli.

A second strain of cocci causing arthritic symptoms was obtained some months later from the throat of a patient with a typical case of acute articular rheumatism. The growth in bouillon was

cloudy throughout with granules floating in the media. The blood serum tubes contained white colonies of staphylococcus albus and fine colonies of streptococci.

On May 19, five c.c. of the mixed bouillon culture twenty-four hours old were injected into the ear vein of a rabbit. Three days later it appeared lame in the left fore leg, the elbow joint of which was slightly swollen. The following day an autopsy was made. The joint was swollen and filled with a nearly clear mucilaginous fluid. Stained smears of the fluid showed it to contain rather few leucocytes, mostly eosinophiles. A few diplococci were also seen. Cultures from the heart blood, joints and periarticular tissue were made, the tubes from the heart remaining sterile. From the joint six bouillon tubes showed a growth which microscopically proved to be a delicate diplococcus, though a few formed short chains. This organism was also found in the tube inoculated with periarticular tissue. On lactose, maltose, and mannite the organism grows without the production of gas. Hiss' inulin medium is not coagulated. On agar there is fine transparent growth which after a week turns slightly whitish. Loeffler's blood serum showed no growth. Litmus milk is acidified and finally coagulated. Five c.c. of a twenty-four hour bouillon culture of this organism was injected into a rabbit's ear vein. Five days later there was a slight swelling of the left knee which cleared up in a few days without further extension.

Briefly summarized the characteristics of the organism obtained by us from the throat of a case of acute articular rheumatism and isolated in pure culture from the joint of a rabbit in which it had produced a polyarthritis, may be described as follows: (1) Culturally it possesses no features by which it may be readily distinguished from other diplo- or streptococci. (2) It possesses special affinity for joints, as a rule attacking several successively, and in a lesser degree for other serous membranes. This is shown by the fact that ten out of the eleven rabbits injected had a polyarthritis, the other dying of pericarditis and pleurisy after a two weeks' illness. (3) That it sometimes produces pus in the joints with disintegration of the joint itself. In all the animals of the first series the joint fluid was somewhat turbid and rich in cellular elements, particularly leucocytes. This was more marked than in any fluid obtained from the joints of a case of rheumatism in man. In the second series the fluid contained fewer cellular elements and was comparatively clear. (4) That though occasionally producing pus in the joints, no pus was found elsewhere in the body, a remarkable fact if we consider the organism to be an ordinary pus producer. The natural result of the injection of such an organism into the circulation would be a pyemia with miliary abscesses throughout the body. (5) That in a majority of cases the course of the disease caused is toward spontaneous cure. (6) The dose was proportionately much greater than one would expect to gain entrance to the human body at any one time, and consequently the more serious results, such as joint disintegration, may possibly be attributed to an invasion of the articular tissues by an overwhelming number of cocci. (Five c.c. were commonly injected into a three to five pound rabbit. A corresponding dose for a one hundred and fifty pound man would be one hundred and fifty to two hundred and fifty c.c., given directly into the blood stream, a condition which would practically never obtain.)

Conclusions.—Our findings in regard to the fluid from rheumatic joints in man agree with the results obtained by other investigators. The joint fluid is sterile not only when planted on culture media, but to the more delicate test of injection directly into the circulation of a susceptible animal. Whether the arthritis caused by our organism be rheumatism in the sense that the arthritis of acute articular rheumatism is, remains "not proven." Certainly a poylarthritis uniformly caused by a distinct organism, tending to spontaneous cure, and with an additional tendency to attack the heart and serous membranes, presents a clinical picture very similar to that of acute articular rheumatism in man, even though a certain proportion of the cases go on to pus formation in the joints. This latter outcome though one of the infrequent eventualities in man, is yet a distinct possibility, and were the invasion made by an overwhelming number of organisms might result more frequently.

We cannot claim with certainty to have isolated a specific coccus, that is, specific in the sense that it will cause the disease known as acute articular rheumatism, but an affinity for the joints our organism certainly possesses. Furthermore, in view of the slight cultural differences between the two strains isolated by us, both causing arthritis, it seems possible that rheumatism may be caused not by a specific coccus, but by a coccus group intimately allied, though perhaps indistinguishable from each other, by our present cultural methods. The individual strains would vary greatly in virulence in its effect both on animals and man. Such a group might well contain the ordinary harmless streptococcus, a common habitant of the tonsil, so many of which were injected in our experiments into the animal circulation without producing symptoms; include a variety causing an arthritis which tends to spontaneous cure unless the number of the invading host be too great, and range up to the malignant streptococci, causing septic joints, septic endocarditis, and pyemia. We have not far to look for an analogy. In the colon group of bacteria we recognize a family ranging from the ordinarily harmless colon bacillus, through the paracolons and paratyphoids to the typhoid bacillus. Yet typhoid fever, as a clinical entity, may be caused by several of these allied strains. Why might not rheumatism be caused by a similarly allied group of cocci? This view could well explain the slightly different cultural reactions reported by the various authors who claim to have isolated the specific coccus of rheumatism, and at the same time be not altogether at variance with the views of those investigators who believe rheumatism to be due to the ordinary pus cocci attenuated.

The older ideas of the etiology of rheumatism, taking no account for the present of the predisposing causes, such as exposure to cold, dampness, etc., its slightly greater frequency among males, seasonal influences, etc., may be grouped roughly into two classes, the Metabolic Theory, and the Nervous Theory. Of these the first is obviously suggested by the similarity of gout to rheumatism; in fact, the two were first separated by Sydenham. As the uric acid is the product of the faulty metabolism of the former, so Prout has suggested that lactic acid is at fault in the latter. Richardson claims to have produced rheumatism by injection of the latter acid, but his experiments have not been confirmed. Haig[17] suggests that uric acid itself is the cause, but it seems at least doubtful, if one distinct chemical body can produce two diseases with such a distinct pathology as gout and rheumatism. The nervous theory was first advanced by J. K. Mitch-

ell,[18] based on the analogy of rheumatic joints to the arthropathies of spinal diseases, but again the absence of trophic change in the joints argues for an entirely different etiological factor. This then leaves us the consideration of the third theory, that of bacterial causation. We have already reviewed the experimental work done in this field by various investigators, but we have yet to consider the reasons deduced from clinical experience for considering rheumatism a bacterial disease. Exposure to cold and wet has long—and I think rightly—been held as a potent factor in the causation of rheumatism; but for as long a time its place in the etiology of pneumonia was just as strong, if not stronger; yet the pneumococcus is now the acknowledged cause of pneumonia, while exposure is relegated to the rôle of lowering body resistance. Why may it not play the same part in rheumatism, giving the bacterium a chance to attack the temporarily unprotected organism?

As to the influence of age, it is a well-known fact that rheumatism occurs with greatest frequency in adolescence and young adult life; in other words, during the period of growth in man when the organism seems least able to combat the infectious and germ produced diseases. In regard to heredity and predisposition, one has only to think of the fight waged for years about the tuberculosis question, where, with the organism known and isolated, the displacement of these fetiches has been accomplished only during the last decade. The fact that rheumatism occurs in epidemics is an old clinical observation. Newsholme[19] concludes that it occurs with regular periodicity. Erdleffson,[20] in Kiel, in commenting on house rheumatism, reports 728 cases in 492 houses, a strong argument for its infectious nature. His figures in detail follow: 2 cases in 1 house, 100; 3 cases in 1 house, 27; 4 cases in 1 house, 5; 5 cases in 1 house, 5; 6 cases in 1 house, 1; 7 cases in 1 house, 1. Fiessinger[21] reports a similar condition.

Epidemic diseases are at the present day considered almost certainly infectious, and probably most of them are caused by bacteria, though in view of recent work in protozoan infections it is not well to be dogmatic. A disease which is transmitted by the mother to the fetus in utero is almost certainly infectious. Of such cases a few have been observed of which perhaps the best attested is that reported by Schaefer,[22] in which the mother was taken ill at the end of pregnancy; the child, though strong and healthy at the time of birth, became ill four days after with an attack of typical articular rheumatism. Pocock[23] reports a similar case. Tonsillitis is regarded, according to some authors (Singer) as being in most cases a rheumatic affection. This angina, as is well known, often precedes and is frequently a symptom of acute rheumatism. The percentage is given as about twenty-five. What more natural supposition than that here the invading organism gains its access to the body, or is here overwhelmed by the resistance of the phagocytes, such an abortive attack of rheumatism constituting the ordinary tonsillitis.

Of that common sequel of rheumatism—endocarditis—two forms have been generally recognized: (1) The malignant or septic form, the bacterial origin of which has long been established; (2) The ordinary rheumatic form occurring in the course of an acute attack of articular rheumatism, subsiding and causing later the mechanical valvular changes which damage the circulatory system for life. This in its incipiency cannot be distinguished from the malignant form, and it too often acts as if the infection were of a genuine pyogenic nature. While usually following the joint affection, it may infrequently coincide with or even precede the arthritis, thus arguing that it is merely another symptom of a general blood invasion with the rheumatic poison, or, to be more explicit, bacterium. With the heart the other serous membranes are likewise affected. Many of the simple pleurisies, not alone those occurring in the course of a rheumatic attack, may well be due to the invasion of our supposed bacterium.

The common skin affections, erythema multiforme and nodosum, are generally conceded to be rheumatic, particularly the latter, as Dyce-Duckworth[24] has shown in a number of articles. This relation of skin affection readily lends itself to an argument in favor of a disease the essential of which is a blood infection, the local skin lesion being caused either by bacterial emboli or a local toxin action. Bacteria have been isolated several times, usually the ordinary pus-producing cocci. Rheumatoid affections, such as those following gonorrhea, scarlet fever, typhoid, pneumonia, are nearly all bacterial in nature. Reasoning from analogy we may well incline to the belief that rheumatism proper is also of bacterial origin. Chorea, long a clinical ally, is perhaps most readily explained as a local invasion of the meninges, and Wassermann's success in producing polyarthritis with a diplococcus isolated from the meninges in a fatal case of chorea, would tend to support this view. Finally, the similarity of a rheumatic to a pyemic infection is so great that a number of authors have called attention to it, notably Singer. Both show an irregular fever, the joint invasion corresponding to the metastatic processes. Profuse sweats, early and marked anemia, high leucocytosis, are common to both. In both one finds frequent lesions in the endo- and pericardium, pleura, lungs, peritoneum, and skin. As a result, then, of a careful clinical analysis of the pathology and symptomatology of rheumatism, one is forced to look beyond the common joint affection to gain a clear idea of such a protean disease attacking, to be sure, oftenest the joints, but too frequently skin, pleura, and heart. Granted a point of entry, probably the tonsil, as the frequency of tonsillitis in rheumatism would suggest, the various conditions vaguely called rheumatic, as well as the out-and-out attack of acute articular rheumatism, seem best explained by considering the essential condition to be a blood infection. Assuming this hematogenous origin, the localization of the symptoms is readily accounted for by the bacterial embolus, or local toxin action.

Assuming this latter view to be correct and that rheumatism is a bacterial disease, the nature of the organism at fault still remains for discussion. Evidently, from the work of the investigators previously quoted, there are five possibilities: (1) An infection caused by the ordinary streptococci or staphylococci with their virulence in some way decreased—a view held by Menzer, Singer, v. Leyden, Sahli, and others. (2) Infection by a specific bacillus—Achalme, Thiroloix. (3) A mixed infection with bacilli and cocci. (4) An infection with a specific coccus—Poynton and Payne, Beaton and Walker, Wassermann, Meyer, Lewis, and Longcope. (5) An infection caused by one of a group of closely allied organisms probably diplo- or streptococci, which cause various grades of arthritic trouble. The most common causing those clinical symptoms which we know as articular rheumatism and tending to spontaneous cure: the more malignant causing a septic arthritis, while between are

many intermediate grades causing as many varieties of infection. The main objection to the first of these views is the extreme rarity of pus formation in rheumatism. It is difficult to imagine the ordinary pus producers as causative agents in so severe an infection, and at the same time so weakened as not to produce their characteristic changes. Animal experimentation, too, has been unsatisfactory with these cocci. The second of these theories seems controverted by the rarity of the findings, which should be constant in the case of a bacillus so striking in appearance and so easy to grow. It seems far more probable that a bacillus entering the heart post mortem was isolated. Animal experiments, too, are far from convincing. The third theory advanced by several followers of Achalme may be dismissed for the same reasons. The fourth is the theory that rheumatism is due to a specific coccus. In favor of this is the uniformity of the findings at the hands of a considerable number of observers; but above all is the success of their animal experimentation and the regularity with which by injection of their organisms a polyarthritis is produced. Opposed to it is the failure in competent hands to duplicate their findings. The fifth theory perhaps reconciles the views held by those who believe in the specific coccus with that of those who believe the attenuated pus coccus the causal agent. It is strongly suggested by the results of our own investigations. Our coccus, while resembling that described b Poynton and Payne, occasionally produces pus in the joints, but not elsewhere, while its affinity for serous membranes is at least as great as that described by the above authors. It seems fair, therefore, to consider it a closely related, but not identical, organism.

In conclusion we wish to thank Drs. Kinnicutt, James, and Thacher for their courtesy in giving us access to the material in their wards, and Dr. Tuttle for his valuable advice in bacteriological questions.

CEREBELLAR APOPLEXY.*

By M. ALLEN STARR, M.D., LL.D.,

NEW YORK.

PROFESSOR OF NEUROLOGY, COLUMBIA UNIVERSITY.

WHILE the ordinary types of cerebral apoplexy are familiar to every practitioner and present no difficulty of diagnosis, the existence of cerebellar apoplexy is not generally recognized. It is undoubtedly a somewhat rare affection. In 187 consecutive cases of apoplexy examined post-mortem at the Presbyterian Hospital, hemorrhage in or softening of the cerebellum was found in four cases only. Yet an examination of the literature of the past twenty years has shown that in every country cases have been observed and recorded in sufficient numbers to warrant the assertion that it is a condition which should be recognized and properly treated. The list of references appended to this paper gives 27 cases in which cerebellar hemorrhage has been found after death. There is no question, therefore, of the existence of the affection.

The following cases appear to present the symptoms which are characteristic of this form of apoplexy.

CASE I.—Mrs. R. had a slight hemiplegic attack when 59 years of age, from which she recovered entirely. At the age of 60, in August, she had a sudden attack attended by great prostration, headache, and severe vertigo, from which she recovered very slowly, her feebleness and apparent sense of weakness

*Read at a meeting of the Practitioners' Society of New York, April 6, 1906.

and uncertainty of balance being out of proportion to any objective symptoms. I saw her in March and again in October, all her symptoms remaining during this time without improvement. These symptoms were a sense of unsteadiness and uncertainty of position whenever she attempted to stand or to walk. While seated or lying down she had no vertigo, but any attempt at standing or walking or going up or down stairs produced a sensation of swaying and instability so that she required assistance. When she was steadied by a cane or the arm of an attendant she felt relieved and could walk fairly well. When left alone she staggered and swayed and showed a tendency to fall toward the right side. There was no paralysis or anesthesia; her knee jerks were normal, there was no Babinski reflex. There was no condition of her digestive system or of her aural apparatus to account for her dizziness. The only objective sign of disease was a nystagmus on movement of the eyes in any direction, but this was not accompanied by any paralysis of the ocular muscles or by double vision, and had not been noticed until my examination. When walking her family had noticed that she threw her head back a little in an unnatural position, but this she had not noticed herself. Her symptoms persisted until, a year later, at the age of 62, she died in an apoplectic attack.

Case II.—Mr. P., at the age of 73, was suddenly seized with intense vertigo, and this was followed by headache and vomiting, attended by great prostration. The latter symptoms gradually subsided, and after two weeks he was able to be up and about, but he suffered for three years after, until his death, from constant sensations of vertigo on standing or walking, and he staggered badly in walking alone. He was never dizzy while lying down or when seated quietly, but when he attempted to walk he became unsteady, felt as if he were going to fall and, in his attempts to balance himself, swayed from side to side and walked with an irregular gait. Any physical or mental exertion increased the vertigo and staggering. He occasionally suffered from a sense of pressure and fullness in the back of the head, and from headache, and when these symptoms were present he staggered more and his legs felt heavy. He had no trouble with sight or hearing. His eyes and ears appeared to be normal. But any motion upward of the eyes always produced vertigo, though there was no nystagmus. He had no paralysis or anesthesia. His knee jerks were normal. His digestion was perfect. The condition described remained stationary for three years, during which I saw him occasionally. He then died of apoplexy.

Case III.—Mrs. E., aged 68, was suddenly seized with an attack of vomiting without any digestive cause, attended by intense frontal and general headache and extreme vertigo and prostration. For a week she was confined to her bed with all these symptoms, although she did not vomit after the second day. Then her symptoms subsided, excepting the vertigo and an unsteadiness of gait, which have persisted for two months. When she is seated she is quite comfortable and has no dizziness, but there is a marked tendency for her head to fall forward, so that unless her attention is fixed upon it the forehead tends to sink down. When she turns her head it is held in a rigid position, as if she were suffering from a stiff neck. Yet she can turn it easily. Any rapid motion, however, causes vertigo. When she walks she goes very slowly and carefully, with feet wide apart and an obvious attempt to balance herself, and she feels uncertain in her gait and staggers at times. There is no special tendency to fall in any one direction. There is no paralysis or anesthesia. The knee jerks are normal. Examination showed a marked lateral nystagmus on any motion of the eyes. There is no double vision or paralysis of ocular muscles. The hearing is normal and her digestion is perfect.

Case IV.—Mrs. J., aged 65, while walking on the street was suddenly seized with vertigo and a feeling of weakness in the right side, and succeeded in getting home with difficulty. There was no paralysis of the side, but there appeared to be a lack of power of control and an uncertainty in motion. These symptoms have continued for the past three years. She staggers in walking, has a tendency to pitch forward and fall toward the right side when not supported, moves in a stiff and rigid manner, and turns her head stiffly. When left alone her head tends to sink forward and toward the right, the instinctive balancing action of the trunk and neck muscles seeming to be imperfect. This tendency is constantly corrected voluntarily. There is no change in the knee jerks and no anesthesia. The condition is stationary. There is no nystagmus.

Case V.—Mr. W., aged 28 years, a fairly healthy, vigorous, and active man, who had had syphilis five years before, was suddenly seized while walking on the street with a sense of prostration and intense vertigo and loss of balance, so that with some difficulty and with the aid of a bystander he got into a shop, and from there was taken home. He noticed immediately after the attack that all objects appeared to be double, one object being considerably above the other, and this double vision being more intense when he looked toward the right. He was confined to his bed for a week. Was able to sit up at the end of a week, but found himself still very giddy. By the end of the second week double vision had ceased and since then he has had no return of it and there was at the time of my examination no evidence of any defect in the ocular movements. For the past three years the sensation of vertigo has continued, being somewhat intense when he is exhausted, or when he has attempted to do any mental work, and less intense when living a quiet country life. Nevertheless it has never ceased, and it practically incapacitates him from his work as a lawyer. He does not stagger in walking, but he feels as if the floor were uneven and was going up and down; describes the sensation much as one would feel in walking on the deck of a rolling, pitching steamer. In other respects he is apparently in good health, although this vertigo annoys him constantly, as it depresses his spirits. He is anxious to do his work and is ambitious. He has had thorough antisyphilitic treatment with inunctions and large doses of iodide and tonics during the past three years, has visited various health resorts, has traveled, and has had the best of treatment without any relief whatever, and the condition seems to be at present a permanent one.

In this case it is probable that some obliterating endarteritis in the cerebral vessels of syphilitic origin had led to a thrombosis in one of the cerebellar arteries, and consequent softening. Cases of cerebellar softening having been recorded at autopsies, though with less frequency than those of cerebellar hemorrhage.

The symptoms common to these five cases are vertigo, of an extreme degree at the onset, subsiding to some extent gradually, but recurring on any attempt to walk, and remaining as a permanent symptom; an uncertainty in gait due, not to paralysis, but to a lack of balancing power, which results in staggering and uneven steps; an unnatural posture of the head when at rest, and nystagmus.

These symptoms when in combination are characteristic of cerebellar disease.

Much attention has been paid in recent years to diseases of the cerebellum, particularly to cerebellar tumors, which are not infrequent; and the symptomatology of cerebellar disease is well established.*

There is no doubt that the cerebellum is the organ of equilibrium. The maintenance of equilibrium is a function in constant use—for no matter what posture is assumed, no matter what kind of a muscular exertion is performed, some compensatory balancing action is called into play adjusting the automatic contractions of the neck and trunk muscles so that the center of gravity shall be preserved. If one watches the growth of a child and the process of learning to stand and to walk and to climb one becomes convinced that these automatic acts, which in adults are carried on below the level of consciousness, are at the outset acts of consciousness and of voluntary effort. As practice has made them perfect they cease to be conscious. But let some disease impair the mechanism and at once the defect becomes conscious, and an effort to compensate for the defect leads to voluntary attempts to preserve or adjust the balance leading to a sense of uncertainty and an effort to preserve the center of gravity. The cerebellar gait is the symptom which results and which differs from all other gaits in disease.

The sense of complete prostration and inability to attempt to rise from the bed is probably due to a suspension of function of the centers of body equilibrium which lie in the cerebellum. This prostration seems to differ from the nerve exhaustion of the shock, for it is not present in cerebral apoplexy. It is different from the exhaustion due to weakness or to heart failure, for none of the signs of these conditions seem to attend it. It is to be explained as the mental appreciation of the loss of equilibrium and as characteristic of cerebellar disease. Babinski has named it "asynergia," and maintains that it may be unilateral, the sense of weakness, inability to balance, and to hold up the body being greater upon one side, and being a transient symptom in cases of tumor. This hemisynergia was well marked in my case IV.

A part and parcel of the balancing process lies in the relation of the head to the trunk. Incline the head far forward or backward and hold it so and then attempt to walk or to pick up an object from the ground and one realizes at once the importance of proper posture of the head in preserving the balance. It has been noticed by many physiologists that extirpation of part of the cerebellum leads to abnormal positions of the head, and in the study of brain tumors it has developed that tumors destroying the forward or cephalic part of the middle lobe have been attended by a falling forward of the head, while those that destroy the back or caudal part of the middle lobe lead to a falling backward of the head. In Case I. the patient carried the head thrown back. In cases III. and IV. the head inclined forward.

Batten† has attempted to show that a lesion of one half of the cerebellum causes a lateral turning of the head, the ear on the side of the lesion being brought down to the shoulder and the chin being turned up and away from the side of the lesion. If this proves to be so, it shows that the cerebellum has a function in determining the position of the head. And it makes any abnormal posture of the head when maintained for some time a valuable symptom of cerebellar disease.

All physiologists who have experimented on the cerebellum have found that irritation of the organ by electricity produces movements of the eyes. These are usually conjoined movements, as single muscles of the eye cannot be excited to action from the cerebellum. In tumors of the cerebellum nystagmus is often observed as an early symptom. And while in some cases this may be due to irritation of the oculomotor centers by distention of the Aqueduct of Sylvius by fluid in the ventricles, in other cases it is undoubtedly a direct cerebellar symptom. Nystagmus was present in two of the cases here reported, and in a third case it was noted that attempts to look upward caused vertigo. This then is to be regarded as a valuable sign of cerebellar disease when taken in conjunction with other symptoms.

The vomiting and headache observed in all the cases are doubtless due to irritation of the vasomotor and pneumogastric centers in the floor of the fourth ventricle, which lies immediately below the cerebellum.

It seems easy from these considerations to recognize the existence of cerebellar apoplexy from its characteristic symptoms.

This has an important bearing upon treatment. I have found that in many cases the diagnosis made of attacks of vertigo in old people is "stomach vertigo;" that they are purged and starved for a few days and then allowed to get up and go about. If some of these cases are really cases of cerebellar apoplexy it is evident that they should be treated as cerebral apoplexy is treated. They should be kept quiet and not allowed to get up under three weeks from the attack. Arterial conditions must be attended to and all effort be avoided. There is no need for special attention to the stomach, for the vomiting is not due to any stomach disturbance, nor as a rule are laxatives required. Bromide or antipyrin may quiet the symptoms of vertigo if this persists. But as the symptom of staggering is due to the lesion it cannot be reached by treatment any more than can a hemiplegia or hemianopsia in cerebral apoplexy.

THE STATE AND TUBERCULOSIS SANATORIA.

By MELVIN P. BURNHAM, M.D.,

RAY BROOK, N. Y.

ACTING SUPERINTENDENT NEW YORK STATE HOSPITAL FOR TUBERCULOSIS.

The problem of the suppression of tuberculosis is, beyond doubt, the business of the State to-day. We have now at hand sufficient information concerning the disease to enable a body politic to rid itself entirely of the scourge, if measures conforming to the known facts are rigorously put into force. The subject as a whole may be divided by the State into two divisions; one of which has for its object the curing of tuberculosis, and the other (the more important, from the standpoint of the masses), its prevention. For a decade and more, even, the State of New York, though the leader in antituberculosis work in all lines, with the facts well known, has done little or nothing, as proved by the annual death-rate from tuberculosis for the entire State. The law must lend itself to the problem, and will do so before anything is done to make tuberculosis a disease that can be considered to be under any degree of control. State laws must finally come, and until they do the work of the few men in the medical profession, working along these lines, can have no results of moment; but it is of the curing of tuberculosis from the point of view of the State that I wish to speak in this brief paper.

At the present time some eight or nine States are actually operating sanatoria or partially supporting such institutions managed by private corporations. A few others have funds and laws for the establishing of sanatoria, while many (about half the States in the Union) are agitating the question before their respective legislative bodies. However, during the past year especially, much has been said against sanatorial treatment by men whose opinions are not to be disregarded. Criticisms have been made by physicians in England, particularly after careful scrutiny of published results obtained in their own sanatoria, and they reflect on the soundness and advisability of sanatorial treatment. Some say sanatoria do not pay; some say they are unnecessary and extravagant; some say that the situation may be met in a more practical way. This discussion has related mostly to the treatment of the poor consumptive, and the various conclusions are likewise drawn from the standpoint of the usefulness of sanatoria for the poor. For this reason it seems to me that very careful consideration ought to be given by a State, in the treatment of the poor, primarly, to the endeavor to cure (and no other course can be justified when for the enormous number of consumptives the extreme limitation of available beds in sanatorial treatment is considered), and it is well, if possible, to show plainly where the trouble is in the situation in order that a State may not enter into an impracticable undertaking. To meet the enormous problem of eradication of tuberculosis will of necessity entail a large expenditure of public funds, and the amount applied along this line must be judiciously expended to secure the approval of the laity as well as of the profession.

The high per capita cost to-day of the treatment of consumptives at sanatoria, as shown by the various reports of sanatoria operating in different parts of the country, makes it highly necessary to show definite results of sufficient value from the point of curability to obtain the good-will of the lay public and consequently funds sufficient to carry on this line of the work.

I wish to show now, as well as I can, what is to be expected of sanatorial treatment as practised to-day in this country, and beg to call attention to the following published statistics found in the last annual reports of the following representative sanatoria treating the poor mainly, and in particular I wish to bring to notice the class of cases treated, the maintenance cost per patient, and the results obtained, and further to consider these facts as related to one another.

* Eighteen cases remained less than one month and are not reported upon.

† One hundred and ninety-four cases remained only about one month and are not considered.

‡ Seventeen cases remained less than one month and are not considered.

§ Twenty-five cases remained less than two months and are not considered.

In interpreting results the great difficulty of comparing work done under different standards is evident. However, the favorable results of treatment divide themselves easily into two classes (as shown by post-discharge observation of sanatorial cases), namely, (1) apparently recovered cases and (2) those of various degrees of improvement, designated on discharge by such terms as "improved," "much improved," and "arrested." The first class, representing those cases which three months prior to discharge have been without symptoms of any kind and with signs in the lung indicative of a healed lesion, or absent, is one in which we may expect ultimate recovery in a large proportion of cases, as is now well proved by experience, and for this reason this class furnishes a very positive factor for consideration. The second class, though composed of cases which have all improved as a result of sanatorium treatment, cannot be considered to have obtained anything more than temporary benefit in the great majority of instances. The disease has become quiescent in many cases, to be sure, but with the return to home surroundings, and perhaps to work, relapse occurs, and for this reason the end results of treatment are unsatisfactory. It has been the latter class of cases—and this class is by far the largest to-day, composing three-fourths of all cases discharged from sanatoria—which has brought down the criticism of the profession on the sanatorial treatment as now administered. This result is the usual result ob-

tained now in most cases sent to sanatoria for treatment. Some have said that lives were really shortened by sanatorial treatment, but this I cannot credit, though, if true, one cannot but wonder at the real good, if any, gained by the general run of cases resident at sanatoria.

From these results it will be seen that of 1,822 cases treated at eight of the representative sanatoria 16 per cent. were discharged apparently recovered. In other words, as a curative measure sanatorium treatment proved successful in only sixteen cases in a hundred. Of this number, judging by final results, computed by adding the comparatively few that ultimately recover of those discharged arrested and those leaving sanatorium before a sufficient stay to allow their being classed otherwise than improved, and deducting the per cent. shown to relapse by post-discharge observations now recorded, twelve in a hundred are ultimately cured, or out of 1,822 cases treated 219 will be cured. Of the remaining 1,603 a few are to be expected to recover, as noted above, and to many others great relief is given, and this is not to be disregarded in putting a value on treatment. Many arrested cases, those occurring in the more advanced lesions, as a rule, are able to return home and to work for various periods of time. Others will reach a degree of health compatible with certain grades of work; a few will remain chronic invalids, and many will die. Few die in sanatoria for obvious well-known reasons.

If we consider the small number of cured cases, in view of the enormous expense and extended time of treatment, I do not think a State is justified at this time in operating sanatoria for this class of cases taken as a whole. The treatment of incipient disease, however, shows such a great difference in results that I believe other conclusions may be drawn, and bearing upon this point I wish now to call attention to the following table.

	Number of Incipient or Early Cases Treated.	Apparently Recovered.
Adirondack Cottage Sanitarium, Saranac Lake	90	34–37.7 per cent.
Gaylord Farm Sanatorium, Connecticut	6	0–0 "
Loomis Sanatorium (Annex), Liberty, N. Y.	22	11–50 "
Massachusetts State Sanatorium, Rutland	199	78–39.1 "
Montefiore Home Country Sanitarium, Bedford Station	126	38–30.1 "
Muskoka Free Hospital for Consumptives, Canada	23	4–17.3 "
New York State Hospital for Treatment of Incipient Pulmonary Tuberculosis, Ray Brook	87	63–72 "

Of 553 cases treated in the incipient stage, 228 on discharge are designated as apparent recoveries, or 41.2 per cent. This is below what is generally accepted to be the proportion expected to recover when incipient disease alone is treated, namely, 75 per cent., and is probably explained by the fact that certain cases in this number are included as incipients which do not rightfully belong in the class, but are in various stages of more advanced disease. Making the same deduction from this number as above, and adding the few ultimate recoveries that may be expected to occur in the cases discharged arrested, and in those leaving before the period of three months in sanatorium, which is the only factor barring their being classified as apparently recovered cases, the total number of apparent recoveries is nearly 50 per cent., or one-half of all incipients treated. Accepting that figure, though it is 25 per cent. less than ought to be obtained in the treatment of this class of disease by sanatorial methods, and noting that one institution, founded for the sole purpose of treating incipient disease, reports for its first year's work 72 per cent. of apparent recoveries in incipient cases, the result seems, from the point of view of social economy alone (and with regard to this must all work toward the eradication of tuberculosis be administered) profitable to a State to a very considerable degree.

The average weekly per capita cost for sanatorial treatment of the poor, as shown by the above table, is about $9.00, and, although this exceeds, by a large margin, the cost of any other institution treating disease, operated by a State, it is entirely practical when one considers the results that may be obtained when sanatorial treatment is properly administered. Considering the above results, the high per capita cost and the extended time necessary for the treatment, if it is to prove lasting, there is only one conclusion to be drawn, namely, that for the consumptive poor sanatorial treatment is indicated only in the incipient stage of the disease and should be practised by a State only in this class of cases. The above reported results substantiate those of the work of others in the same line as nearly as can be determined by comparisons, and conclusively show that for a State to be successful in the work, it must, as the first and most important measure in the application of treatment, demand that the tuberculosis be in the incipient stage only, as a requirement for admission to sanatoria. This will be proved beyond doubt in a short time by States operating sanatoria, and the State which recognizes the urgency and extreme advisability of the procedure will be sure of cordial support in its work. On the other hand, a sanatorium not doing so will gradually cease to be what it was intended for and become a hospital for chronic and incurable disease, and as a result must expect the same support as is given these institutions now being operated by a State, and rightfully so. We are immediately met, upon arriving at this conclusion, by the statements that incipients are hard to get, that the poor do not report to the physician at this stage of the disease, and that the general practitioner would not recognize them if they did, all of which is more or less true; but until the incipient disease is known to the profession as the only curable form of pulmonary tuberculosis, surely it will not be recognized. Incipients must be had. When it is demanded of the profession that they diagnose incipient tuberculosis because it is a curable disease and curable only in this stage, then and then only will such a disease be routinely recognized. As it is now, with sanatoria accepting any stage of consumption, and at a high rate of cost trying to accomplish the impossible, the generally unscientific aspect of the procedure is only too palpable, and the people will see it if the profession do not.

As long as this condition exists, the general practitioner will let the incipient patient go contentedly by and send him away to die in a resort supposedly favorable to the cure of tuberculosis, or to live a life of chronic invalidism away from home and relatives. A State by law may establish sanatoria and can limit the treatment of tuberculosis to the incipient stage of the disease, and by so doing not only do great good in actually curing tuberculosis, but incalculable good by educating both the profession and the public. The *laissez faire* policy of the past is now becoming ridiculous, if not to say harmful. The entire subject of meeting the problems presented by tuberculosis and treating tuberculosis as a disease of the masses, is likely to come into bad repute, if it is not met and measures are not taken which have

proved to be most valuable. At this time, though incipient disease is not generally recognized because in the past no such demand has been made upon the profession, New York State, in its institution for the treatment of incipient tuberculosis, has 70 per cent. of all cases under treatment in the incipient stage. The law whereby this condition was made possible is one which other States may well follow, and to Dr. John H. Pryor of Buffalo should be given the credit for the law drawn by him in 1900, and along the lines of which this institution has been organized. This law has proved eminently satisfactory, and there can be no doubt that a State, to be successful, must have such a law before a sanatorium can be successfully operated. Other factors for the State to observe, in selecting cases for sanatorial treatment, are the social conditions and the probabilities in the after life of accepted patients, supposing that favorable result has been the outcome of stay in a sanatorium. The lowest grades of society will furnish few suitable cases for sanatorial care. The inherent ignorance of the patients will prove such a stumbling-block after a god result has been obtained at the sanatorium, that absolute inability to secure proper life after discharge will mean relapse and will consequently negative any good accomplished at the sanatorium. Another class, though of sufficient intellect (and this is a very large class), will on discharge be unable to regulate their lives as instructed, and consequently will be liable, though to a less degree than the former class, to either relapse or subsequent attacks of tuberculosis. It is useless to teach a mode of life to the patient if he cannot follow it out after discharge. To this large number relief must be in some way furnished, and proper care, observation, and advice given them for the critical period of two years following discharge from the sanatorium. In a few years, as it becomes widely known that incipient disease among the poor is the only stage in which curative measures are of avail, it will become, I believe, a fact that sanatoria for the treatment of these cases will cease to be the highly expensive organizations that they are at present, and will in a large degree be self-supporting. The rejection of all but incipient cases will make it possible to operate with little expense for administration beyond the help as provided by patients themselves; and in the treatment of this class of cases all the ideas of forced feeding, absolute rest, etc., will be entirely out of place and consequently will not call for large expenditures. This will not only be a saving, financially, but will make the medical treatment at the sanatorium more successful and valuable in the end. One of the mistakes to-day in sanatorial treatment arises from the fact that patients lead a life of idleness, which is harmful in many cases, and on return to their homes, soft and fat, the least fatigue on taking up work is apt to be harmful. Patients who are treated in a hospital where they do a certain amount of work daily, under observation, are in much better condition to return to their homes to work than if such had not been the case. They know about what they can do. The change from a life of ease in a health resort to one of work in a large city is not what it should be, as I believe many observers among physicians will testify.

The farm colony system, the ideal theoretical method to-day, will, under these conditions, be thoroughly practical, and the cure of tuberculosis will then become such a factor as to be of value equal to what prevention might be to-day if carefully regulated by law. Such a condition is now on the verge of fulfillment by the City of New York, the pioneer city in antituberculosis work in this country, and Commissioner Darlington's Camp, about to be established, will be the first of its kind in America operated on the plan as outlined above.

Many statements made in this paper concerning the cure of tuberculosis do not apply to the well-to-do consumptive patient. Such a patient may still recover from a marked lesion in the lungs by giving long time and great care to it, and others may enjoy the luxury of a chronic pulmonary disease and by means of their wealth endure life for many years; but the poor consumptive must be diagnosed when his disease is incipient and be cured by law.

The question of taking care of the many advanced cases and of the methods to be employed offers great difficulties. Present measures are totally inadequate to meet the demands, owing to the overwhelming numbers in this advanced stage. Provision must be made for care of the advanced cases, under proper supervision in hospitals near the large cities, for many years to come; but with the enactment of laws of prevention and the recognition and cure of the incipient disease at sanatoria, the subject of their care will not require any large amount of attention.

The State of New York was the first to establish a sanatorium for the treatment of incipient pulmonary tuberculosis exclusively, and it has proven beyond doubt the advisability of so doing by the high percentage of favorable results obtained in treatment. As a first requisite I think other States should follow the example set in this work by New York, and they will reap the expected results, which will be eminently satisfactory, not only from the standpoint of the State, but also from that of the individual and the profession.

ATROPHIC CIRRHOSIS OF THE LIVER, WITH REPORT OF TWO CASES.

By W. L. WASSON, M.D.,

WATERBURY, VT.

ASSISTANT PHYSICIAN AND PATHOLOGIST OF THE VERMONT STATE HOSPITAL FOR THE INSANE.

Cirrhosis of the liver, a term introduced by Laennec, descriptive of the contracted form because of its yellowish appearance, is characterized by an increase of connective tissue within the liver, and is attended by symptoms which vary according to the distribution of the new connective tissue within the organ. The new tissue may have chiefly an intralobular or an interlobular arrangement, and in some cases there is a combination of both types.

There are various forms of cirrhosis, clinically and anatomically considered, leading to several different classifications by various observers. Chauffard's arrangement, based on the anatomical changes and etiology, is here given. It is as follows:

I. VASCULAR.

(1) Toxic Form { Poisons taken into the stomach. / Autochthonous poisons.

(2) Infection Form { By direct action of microbes. Local action. / By toxic infection Extrahepatic.

(3) Distrophic Form { Arteriosclerosis. / Subhepatic stasis.

II. BILIARY CIRRHOSIS.

(1) Hypertrophic Cirrhosis of Hanot.
(2) Calculous Cirrhosis.

III. CAPSULAR CIRRHOSIS.

(1) Chronic Localized Hepatitis.
(2) Generalized Perihepatitis.

The agents that precipitate an increase of new tissue in the liver may be formed within the organism itself or taken into the stomach. In either case they reach the liver by means of the blood-vessels or lymph channels, and, according to some, occasionally by means of the bile ducts.

Alcohol is generally considered to be the most potent agent in bringing about cirrhosis, whether taken in small quantities, long continued, or in excess. It is claimed that 15 per cent. of all cases are due to alcohol and that 4 per cent. of those addicted to the excessive use of alcohol have cirrhosis. W. B. Cheadle says that contracted liver is nearly always alcoholic in origin. Osler thinks beer and wine are especially answerable for the fatty form. The action of alcohol seems to be greater when taken before meals.

Other agents bringing about this condition are syphilis, malaria, tuberculosis, lead, copper, pigmentation (Welch), passive hyperemia, biliary obstruction, acute infectious diseases, and poisons formed in and absorbed from the alimentary canal. It has been produced experimentally upon different animals by a variety of bacteria. According to Segers, the inhabitants of Terra del Fuego suffer from an intoxication in which the liver is chiefly affected. This condition is attributable to the ingestion of mussels whose livers contain the toxic agent.

Atrophic cirrhosis was recognized as early as the time of Morgagni, but, as above stated, we are indebted to Laennec for the term cirrhosis, which is now quite generally employed when describing a condition where connective tissue is increased. Atrophic cirrhosis is also called venous cirrhosis in contradistinction to the biliary form. Osler designates two types, the small atrophic and the fatty. It usually occurs in those of middle age and of alcoholic habit. Whiskey, gin, and brandy have greater influence as causative agents than beer. Young children not rarely have been found to suffer from this condition of the liver, usually following alcoholism, syphilis, or infectious diseases.

Strümpel, Graham, and most of the German pathologists speak of two stages: first, a swelling and enlargement of the organ, followed by a contraction of the new-formed tissue and a reduction in size. Others claim there is no certainty that this change occurs, and are inclined to the belief that no preliminary swelling takes place. Hanot and Gilbert state that they have never seen a case of alcoholic cirrhosis enlarged during the early stage that subsequently contracted. The organ when observed at the autopsy is generally small and contracted, although in the fatty type it may be enlarged.

The pathological changes may be summarized as an increase of connective tissue, atrophy of the liver cells, increased number of bile radicles, and obstructed portal system. These changes will be considered more at length anon.

The symptoms during the early stage are usually slight and point rather toward dyspepsia than anything more serious. Later, when the portal system becomes compressed, there ensues the onset of a graver condition.

At first there is nausea and vomiting, especially marked in the morning; this is followed later in the day by an increase of appetite. Ingestion of food is usually attended, shortly after, with discomfort and pyrosis. The bowels are irregular in action, sometimes constipated, sometimes loose, and a yellowing of the conjunctiva may be noticeable. These are symptoms of which alcoholics in general may complain, so that the diseased liver may easily be overlooked for months. Later, as the obstruction to the portal circulation increases and the hepatic functions become deranged, there ensues a definite series of symptoms.

As a result of portal obstruction, provided there is not adequate collateral circulation developed to compensate, ascites appears. In many cases, however, according to Hanot, peritonitis brings about the ascites. Ascites occurs in about 80 per cent. of all cases. The onset of ascites is not marked by any special symptoms. The first thing to attract attention, perhaps, is an increasing distention of the abdomen, more marked after meals. Acute cases may rarely occur in which the accumulation of fluid is both rapid and extensive. The quantity varies in different cases up to ten, fifteen, or even twenty liters. When large quantities of fluid are present within the abdomen, examination of the liver is difficult. It may, however, be felt by exerting sudden pressure with the fingers (Dipping). Enlarged spleen is likewise difficult to determine. Its increased size is due both to passive congestion and diffuse hyperplasia of tissue.

The presence of fluid in the abdomen can be determined easily by the usual symptoms; viz., fluctuation and change in the area of dullness when the patient assumes different positions. It remains throughout the disease after its inception, the quantity varying according to treatment and state of the venous anastomosis.

The abdominal subcutaneous veins are dilated, forming about the umbilicus the characteristic caput medusæ.

The urine is scanty during the ascitic stage, contains an abundance of urates, is of high specific gravity; its urea is reduced and uric acid is increased. At times albumen is present, due to congestion of the kidneys and cachexia. The presence of casts, or intense jaundice, indicates nephritis. Bile pigment may also be observed. J. Marischler and E. Ozarkiewicz report a loss in the excretion of phosphates as peculiar to cirrhosis.

Jaundice is not a marked feature, although W. B. Cheadle contends that this symptom is relatively frequent. Fagge reports it present in 35 out of 135 cases. Most frequently the only indication of jaundice is a slight icteroid tinge of the conjunctiva or skin, and when pronounced, jaundice is more likely to be due to catarrhal cholangitis, or compression of the common bile duct from external adhesions, rather than from pressure within the liver (Graham).

As a result of the passive congestion of the intestinal mucosa from the obstructed partal circulation, oozings, in greater or less amount, from the dilated capillaries, are of comparatively frequent occurrence. Copious quantities of blood may be vomited. Melena following gastric hemorrhage is common, and intestinal hemorrhage may exist over a long period without hematemesis. Fatal hemorrhage may result from rupture of the dilated varices about the lower end of the esophagus, and, in one case observed by the writer, the hemorrhage was beneath the right pleura in sufficient quantity to cause death.

Fever is usually absent, but may be present in some cases, due, very likely, to catarrhal inflammation of the bile ducts or perihepatitis.

Respiration may be embarrassed by pressure from the distended abdomen or from pleuritic effusion. The general nutrition suffers greatly, so much so that the emaciated appearance of the face, chest, and limbs, in contrast to the distended abdomen, is characteristic. The eyes are watery, face thin, vessels of nose and cheeks distended, and skin icteroid (hectic facies).

The heart action is often weak, pulse of low tension, and position of heart changed, owing to pressure of fluid within the abdominal cavity.

The digestive functions, as is obvious from chronic congestion of the mucous membranes of the alimentary tract, are always profoundly affected. Fermentation of stomach contents, nausea, and vomiting are frequent symptoms, especially marked in the morning, and no doubt due to the collection of mucus within the stomach.

After a course of one or more years, death is the usual termination, although in some instances recoveries have been reported. Under proper treatment, early instituted, other patients have enjoyed good health for years. Asthenia is the usual cause of death, but it may result from hepatic uremia or hemorrhage from a ruptured vein.

Among the complications which may attend cirrhosis and which arise from the same cause—namely, alcoholic intoxication—are nephritis, myocarditis, and edema, chronic inflammation of the brain, membranes, and occasionally diabetes. Tuberculosis is frequent, especially of the peritoneum, and in many instances it is the direct cause of death.

It is obvious that, except in a few selected cases taken early, treatment can be of little avail in this disease. Even then all that can be hoped for is that the morbid process may be arrested, for the fibrous growth in the liver remains as such permanently, at the point it had reached when treatment was instituted and the irritating cause removed. Any amelioration of the patient's condition is due to the establishment of a better collateral circulation and maybe to an improvement of the functions of the liver in general.

Alcohol should be interdicted, as well as rich and highly seasoned foods. Milk, if possible, should be the main article of food; soups and a small amount of farinaceous foods may be added. Gastrointestinal catarrh should receive attention, the bowels kept regular, and an attempt made to control the ascites by cartharsis and diuresis in cases in which these measures are not contraindicated. Tapping to relieve ascites is more efficacious, and should be done under strict antiseeptic precautions. Hepatic extract has been given with apparent profit.

Following is a report of two cases, with special reference to the pathology:

Case I.—A man aged 60, a native of New York State, by occupation a bookkeeper. For many years he has been addicted to the abuse of alcoholics. Early in the summer of 1904 he consulted a physician in relation to various digestive disturbances and was treated for the same, without the true nature of his malady being discovered. He continued the daily use of alcohol until a short time before his death. Besides the digestive disturbances, glycosuria was discovered to be present a week or so prior to his coming to us. He lived but two days after having been admitted to the hospital, lying in a semi-stuporous state, rousing occasionally to call for water, but otherwise expressing no wants or display of intelligent consciousness. Three or four days before he was seen by us, he fell down a cellar hatchway and sustained a severe bruise at the inferior angle of the right scapula—the skin being broken and extensively discolored. His decline from this time was both rapid and profound.

Physical examination revealed rapid, weak heart action; small, thready pulse; numerous, whistling râles over both lungs, and on the right side, posteriorly, a flat percussion note; abdomen distended and tympanitic, pupils average size, reacting sluggishly to light. The urine had a sp. gr. of 1020, contained a large amount of albumin, and gave a heavy reaction for sugar. Urea 1.4 per cent., chlorides 5 per cent.; phosphates 12 per cent., blood and bile absent. Microscopically, there were a few epitheliogranular and finely granular casts, numerous dark granular, narrow and broad hyaline casts, a few blood cells

Fig. 1.—Inferior surface of the liver in Case I.

and leucocytes. Shortly before death he vomited a small quantity of chocolate-colored fluid.

At the autopsy he proved to be a regular symposium of pathological conditions. Before entering into a detailed description of the special pathological features of interest, I will indicate briefly what was found, generally. Dura adherent to calvarium, basilar and cerebral arteries atheromatous, right hemothorax, right subpleural hemorrhage, pulmonary edema, milk spots of epicardium, calcicosis of aortic and mitral rings; mitrals much thickened, atheroma of aorta and coronaries, ecchymosis in wall of right coronary, stomach dilated, mucosa at pyloric end containing several small ecchymotic areas; within the intestine a large specimen of tænia saginata; hobnail liver, enlarged spleen, accessory spleen, cystic and sclerotic kidneys, bladder walls thickened and perforated by several foramina leading to cysts; enlarged prostate, slight ascites.

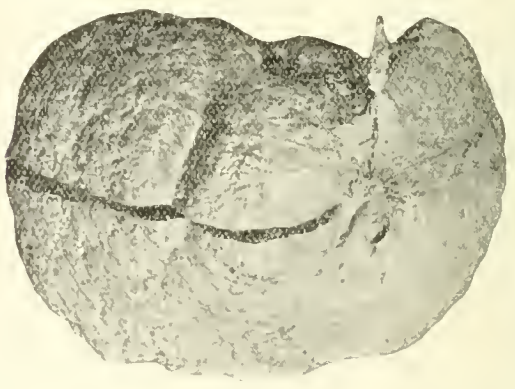

Fig. 2.—Upper surface of the liver, showing nodules and rib sulcus, in Case I.

The liver was removed easily, being free from adhesions; weight, 945 grams; small and rather globular in shape; surface rough, nodular, and inelastic. The nodules were due somewhat to regenerative efforts on part of the liver cells, but mostly from bulging of the lobules as a result of pressure from gradual contraction of the new connective tissue. The consistency was much increased, feeling tough and leathery to knife edge. The cut surface was mottled, exhibiting grayish bands of connective tissue, the interspaces being filled with yellowish glandular tissue. Under the microscope, bands of connective tissue were seen to ramify from

the capsule throughout the organ, encircling groups rather than individual lobules, although it was not strictly multilobular, as here and there strands penetrated between the cells of the lobules (Fig. 3). Scattered collections of round cells occupied at irregular intervals the sites of the portal canals. The con-

Fig. 3.—Photomicrograph, showing bands of connective tissue between lobules.

nective-tissue changes presented the characteristic appearance of a subacute inflammation and seemed to originate about the portal veins, as it is by these channels that the irritating substance is conveyed to the organ. The new tissue was rich or poor in cells, accordingly as it was seen during the early or late stage. Large spindle cells, leucocytes, and round cells predominated, but scattered very sparsely within the new tissue were cells which, with Unna's alkaline methylene blue and eosin stain, gave a darkly staining nucleus, and a cytoplasm composed of large, round, red granules. Mallory's anilin blue connective-tissue stain also gave reddish granules as composing the bulk of the cytoplasm. One giant cell with numerous peripherally arranged nuclei was observed (Fig. 4), and from the presence of this cell, there being no other indications of tubercle, it is fair to assume that giant cells may occasionally exist in the ordinary type of alcoholic cirrhosis. Fibrous tissue was abundant.

The new tissue was richly supplied with blood-vessels, which were distended with blood. The walls of the portal veins were much thickened, but presented no degenerative changes. The smaller branches were obstructed from the contracting tissue, often as well from phlebitis and thrombosis, and the result of this, many times, was hemorrhage either from the stomach or intestine. On the other hand, ascites may develop when a lack of adequate collateral venous anastomosis exists. New bile ducts were fairly abundant, but not markedly so. There have been various theories advanced to account for their origin. The one given by Hamilton is that they come from the nuclei of the atrophied liver cells. "Normal liver cells are to be considered as the expansion of the bile duct epithelium. In cirrhosis they undergo involution and revert to their bile duct embryonic condition." He then proceeds to explain the disappearance of these new structures by a further metamorphosis of their cells into fibrous tissue. Cornil explains the new bile radicles as a growth of new bile epithelium from old ducts along the lines of former capillaries, following the regression of the atrophying lobule.

As a general thing the liver cells were quite well preserved, though many were atrophied, as a result of pressure and a shutting off of nutrition. In many areas near the periphery of the lobule the liver cells were small and spindle shaped from atrophy of the cytoplasm; in other areas, here and there, small vacuoles composed the bulk of the space formerly occupied by cytoplasm (Fig. 5); in still other fields the cells exhibited infiltration of fat collected in large globules. Yellowish granular pigment was generally distributed within the protoplasm of the parenchyma cells. The changes involving the nuclei were peculiar in that many were destroyed, their position within the cell being occupied by a vacuole, the nucleolus showing at one side, and with no appreciable change in the cytoplasm of the cell. The nuclei were double in certain cells, many were enlarged, and still others dumbbell shaped. In many areas might be seen isolated groups of liver cells occupying positions within the broad bands of new tissue, having been cut off from the liver lobule by the infiltrating inflammatory process.

Hamilton contends that a few liver cells, at least, are transformed into connective tissue, thus explaining in part the origin of the new tissue. He exhibits

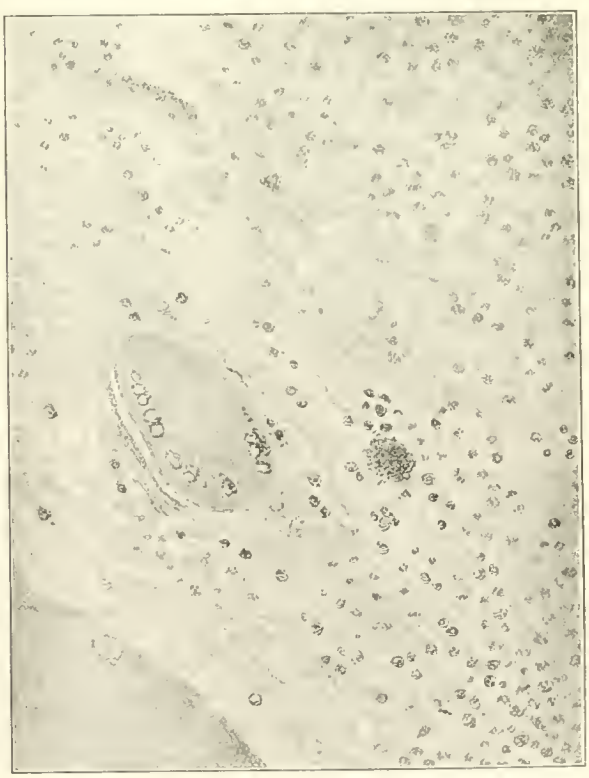

Fig. 4.—Photomicrograph showing giant cell in new connective tissue and round-cell infiltration.

illustrations which would tend to support his assumption, but, according to the teachings of embryology, the liver cells are directly descended from the hyoblastic layer, so it would seem as if a rather startling perversion of type is involved in this hypothesis.

The changes in the pancreas were much less extensive, but analogous to those in the liver; namely, an increase of the interlobular connective tissue. The presence of diabetes would tend to show that the functions of the pancreas had been impaired. H. Strause decided from experiments that liver disease does not produce glycosuria. On the other hand, A. Gilbert and P. Lereboullett report two cases of hypertrophic cirrhosis with diabetes depending on liver disease. H. Sachs holds that liver disease reduces tolerance for levulose, but not for any other sugars. Levulose is the sugar best tolerated in diabetes. Since liver disease affects tolerance for levulose only, disease of the liver is of little importance in the causation of diabetes.

The heart showed round cell infiltration of portions of the epicardium and occasionally of those bands of connective tissue which extended from the epicardium into the muscular structure of the organ. There was, however, no marked fibrosis.

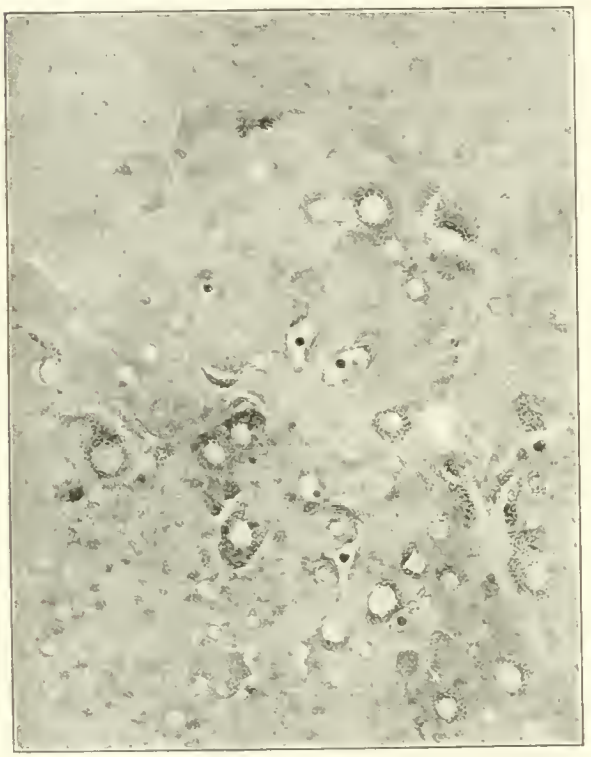

Fig. 5.—Photomicrograph showing vacuolation of nuclei, with here and there a nucleolus present.

Case II.—A woman, aged 71, an inmate of an insane asylum for forty years. She was extremely demented, so much so that all symptoms had to be objectively taken, since little or no reliance could be placed upon her statements. Previous to the onset of her disease, her history was uneventful, except that she was a gourmand at the table. In June, 1902, she suffered from an attack of jaundice, which failed to yield readily to treatment and soon became complicated with chronic tubercular peritonitis. A continuous temperature chart was kept from the inception of the tuberculous condition until her death, in December, 1904. While considerable variability between morning and evening temperature was a constant feature, at times it became extreme—104° in the evening, next morning 97 3-5°. She sustained three exacerbations of jaundice, in March, 1903, October, 1903, and December, 1904, respectively. There was a slight icteroid tinge of the skin and conjunctivæ permanently present. The jaundice was of the obstructive variety, with light stools and choluria. On several occasions during the last attack blood clots were passed in the stools. Between June, 1903, and November, 1904, she experienced some improvement, taking on twenty-five pounds in weight. During her last sickness pain was constant, and, according to her statement, was distributed quite generally over her body; pulse full and strong, ranging between 90 and 105; abdomen distended, tympanitic, and tender, the tenderness being especially marked on right side. The patient succumbed eventually from asthenia.

I will first briefly indicate the conditions of pathological interest found at the autopsy, before describing in detail the changes in the liver. They were as follows: Atelectasis of the two lower lobes of right lung; a tuberculous bronchial gland, caseous and calcareous; aortic atheroma; fenestration of the aortic cusps; thickened mitrals, with calcareous spicule at the base of the posterior leaf; plastic tuberculous peritonitis and subdiaphragmatic tuberculous abscess; hepatic cirrhosis; diffuse nephritis; uterine fibroids.

When the abdomen was opened at the autopsy a peculiar, sweetish, musty odor was noticed. The cavity was free from effusion of serum, but on the right side all the organs were bound together by a thick mass of tuberculous adhesions. A large abscess existed between the diaphragm and the upper surface of the right lobe of the liver. The contents of the abscess were thin, yellowish, and foul. The liver was firmly bound in place by adhesions and was removed with difficulty; weight, 1580 grams of average size, consistency much increased. Its surface was roughened and hobnail in appearance, with tubercles much smaller than in the preceding case, few of them attaining the size of a rice granule. The color of the liver was a dark olive-green, the cut surface mottled by lighter areas of connective tissue infiltration.

Microscopically, the connective tissue was much increased, the arrangement being generally of the multilobular type, but, as in the first case, strands now and then ran into the lobules, separating groups of liver cells and enclosing them. The appearance of the new tissue accorded with the description already given, with the exception that within a narrow zone underneath the capsule at the site of the tuberculous abscess were scattered a profusion of cells having eosinophilic cytoplasm and arranged in granules. Some of these cells contained double or lobulated nuclei, other nuclei being oval and coarsely granular. In many the red granular cytoplasm was widely scattered, as if the cell were undergoing a process of dissolution. Connective tissue cells undergoing a process of hyaline degeneration are, according to Unna, very similar if not identical with the above. Very few were found at any distance from the immediate locality of the abscess.

Round cell infiltration between the liver cells was quite marked, and there was very pronounced fatty degeneration of the parenchyma cells in a large part of the organ. Disposition of bile pigment within the cytoplasm of the cells was another well marked feature. The larger bile ducts were dilated and presented evidences of pericholangitis, and a moderate increase in the number of bile radiles was obvious.

In casting about for an explanation of the cirrhosed condition of the liver, in this case, it is necessary to consider three probable factors—obstructive jaundice, tuberculosis, and alcohol. The woman took a small amount of alcohol each day for a year previous to her death, and it appears possible that the condition of her liver might have depended somewhat on this. On the other hand, so marked was the

tuberculous process about the liver that one is inclined to believe that there was the source of most of the trouble; but the evidences of pericholangitis again attract attention to the obstructive jaundice as a possible etiological factor. On the whole, it seems very probable that the most potent agent here is the tuberculous toxin, the jaundice and the alcohol being accessories, but having much less influence.

CONCERNING THE DIAGNOSIS.*

By JOSEPH N. STUDY, M.D.,
CAMBRIDGE CITY, IND.

The relationship of a correct diagnosis to the practice of medicine and surgery is a matter of supreme importance, and should take precedence of any and all things pertaining to either of these subjects.

Upon the correct diagnosis depends the intelligent administration of therapeutic agents, the proper use of surgical appliances, and all the all-important question of the necessity of operative surgical procedures. In fact, the whole superstructure of medicine and surgery should rest upon the matter of an intelligent observation of facts correctly interpreted. This is a matter we think will be admitted without argument. If there are any proven facts bearing evidence of the virtues of medicinal agents in the treatment of disease and other abnormal conditions of the body structures, then all depends upon knowing the conditions to be corrected.

To the patient so much depends upon the correct intepretation of disease and other abnormal conditions of the body that, in the aggregate, its value could hardly be overestimated. In the early history of medicine and surgery, we surmise, owing to the lack of definite knowledge upon matters of a medical and surgical nature incident to these times, that errors in diagnosis must necessarily have been of frequent occurrence, consequently therapeutic agents, surgical appliances, and operative procedures were, most likely, frequently misused and wrongfully applied.

Naturally one can but think that much empiricism and quackery would have gained a foothold in these early times. At the present time we recognize the fact that opportunities for diagnosing medical and surgical cases have made wonderful advance. In disease, the microscopist and the bacteriologist have taken a recognized position to assist, and in many instances completely supplant, the astute clinician of former times, while the surgeon of to-day, when in doubt, brings to his aid the Röntgen ray, through which the bony structures, the presence of abnormal deposits, and the precise condition of the more important organs and tissues of the body are presented to view—help which the profession at large has eccepted in part, at least, with occasional doubts and misgivings.

When we analyze some of these modern aids to diagnosis, if we can judge by the current literature upon the subject, some of them appear quite limited in their usefulness. In acute lobar pneumonia it has been accepted, in part at least, that to the bacillus of Friedlander is the disease due. In the buccal and bronchial secretions and expectoration of those affected this bacillus is sometimes found, but not invariably so. This same bacillus is occasionally found in the mouths and expectoration of healthy persons. In diphtheria nearly all authorities accept the fact that the Klebs-Loeffler bacillus is the cause of the affection, still there are cases of undoubted diphtheria, in which this bacillus is not found. Then it is a fact that two per cent. of all healthy children's throats contain this specific bacillus. In typhoid fever much has been said of the blood agglutination test of Widal, as well as the diazo reaction test of the urine. These are recognized as helpful methods of diagnosis, but there are times when they give negative results in typhoid fever, especially early in the disease, and sometimes they do, and sometimes do not, give positive indications later in this disease. Unfortunately, the same diazo reaction is obtained in tuberculosis and some other acute and chronic affections.

In early tuberculosis, when so much for the patient depends upon an early interpretation of symptoms, the tuberculin test is frequently wanting or misleading. Of this fact we have the opinion of Dr. S. A. Knopf, who is accredited with saying before the New York Academy of Medicine that the unreliability of tuberculin as a diagnostic agent of value is shown by its producing the same characteristic reactionary symptoms in syphilis, actinomycosis, and ordinary anemic conditions, where no taint or trace of tuberculosis exists. As anemic conditions are so frequently present in cases where tuberculosis is suspected, we should not place too much reliance upon this method of diagnosis.

Blood examinations have come to be recognized as aids in the recognition of abnormal conditions of the body. However, there is more than one condition that may cause a disproportion between the red and white blood corpuscles, as well as modify the percentage of hemoglobin. The Röntgen ray has within recent years become much in evidence as an agent for diagnosing both medical and surgical cases. While its usefulness is acknowledged, there is sufficient evidence to warrant the statement that it is not without its limitations. In regard to the true condition of the various organs and bony structures of the body, abnormal deposits, renal and biliary calculi, its impressions are wrongfully construed at times. Those competent to pass judgment upon the matter intelligently say that in diagnosing fractures and dislocations it is sometimes misleading. Even with the greatest care it has been known to mislead the surgeon. No more impressive illustration of this fact need be given than related by Dr. Janeway, who has reported an instance in which the Röntgen ray had located a plate of false teeth in the esophagus. At the operation no teeth were found, and a careful search revealed them securely placed under the mattress of the bed.

The teaching of this seems to be that it would be unwise to say that an individual was suffering from some disease simply because the specific bacillus was found somewhere in the body, or that the Widal or diazo methods had indicated typhoid fever, or the tuberculin test tuberculosis, and the Klebs-Loeffler bacillus had or had not been found. These helpful methods of diagnosis are somewhat limited in value, and too much dependence should not be placed in them as a class, unless accompanied by the clinical phenomena characteristic of the disease.

The microscopical examination of diseased structures, secretions, and excretions of the body has often made clear a doubtful diagnosis. The making of a correct diagnosis is sufficiently easy in a limited number of cases, and there is no doubt but what this faculty is better developed in some persons than others. There are some persons who would never become expert in diagnosis, regardless of opportunities. Errors are likely to spring up from precipitancy in arriving at conclusions. The practice of diagnosing disease at a glance is to be looked upon with contempt. There are cases very difficult to

*Read at a meeting of the Wayne County (Ind.) Medical Society, January 3, 1906.

diagnose, then there are again cases, for various reasons, that never are correctly diagnosed. One reason why the average clinician very frequently fails in his diagnosis is primarily that he fails to appreciate what constitutes an absolutely healthy body, the location of the different organs, their size, the normal vesicular respiratory sounds and heart sounds, their variation in differently developed bodies, the variations in intensity of pulmonary and cardiac sounds, etc. The full clinical history of any case complete with antecedents is too often omitted. The snap-shot diagnosis is too frequently given. No better evidence need be given than the large number of cases of biliousness alone, which annually visit the doctor's office, as well as the number of deaths from heart failure.

Dr. Gould of Philadelphia has recently called attention to the many conditions diagnosed as organic diseases that were entirely relieved by properly fitted glasses to the eyes. Among such conditions were dyspepsia, persistent vomiting, flatulency, biliousness, migraine, various localized neuralgias, liver affections, constipation, hives, eczema, and numerous other conditions. He says Haig's uric acid condition usually means "eyestrain." He quotes a famous surgeon who says his most brilliant cures of disease of the pelvic cavity, as well as other conditions, have been effected through the oculist.

There are cases presenting many features of angina pectoris, as well as other affections of the heart, that can be traced to the stomach and other conditions in the abdomen. Hysteria may closely simulate true angina. Such a case I have observed for twenty-five years in a woman with frequent attacks, who is still living and in good health. The ashen color of the face during a paroxysm is a better guide than the pulse. Syphilis may closely simulate typhoid fever at certain times, and the resemblance in certain stages between tuberculosis and typhoid fever is well known. An enlarged nodular liver diagnosed as malignant has been known to make wonderful improvement under antisyphilitic treatment. I have heard it said by good surgeons that they believed it impossible to tell absolutely what conditions existed in an abdomen until it was opened to inspection, and sometimes even then not until after an examination under the microscope. This, I believe, is correct. As an illustration, I would cite the following:

Mrs. X, about 60 years of age, American, whose antecedents gave negative information, was the mother of one child, and had been a widow for thirty years. She was of average size, and had enjoyed good health throughout life until the present time. Recently it was discovered that she was having an evening temperature of one or two degrees, and she complained of general weakness, poor appetite, and constipated bowels. Physical examination revealed no disease of any organ or portion of the body, except that, filling the greater portion of the lower abdominal cavity, and most prominent in the line of the lower portion of the descending colon, was an enlargement of considerable size and of semi-solid feel. There was no pain nor vomiting. At the end of thirty days the woman died, apparently from exhaustion. During the patient's sickness a consultant of large experience examined the patient and gave a very positive opinion, which was not shared in by the attending physicians, that she was suffering from impaction of the colon with feces, and resulting autointoxication. The autopsy revealed an empty colon, and the enlargement in the abdomen was due to a cancerous omentum more than two inches in thickness.

I have looked upon the diagnostician with distrust who can invariably make a correct diagnosis in the pregnant uterus at full term, through external palpation, of the exact relative position of the child. Such we read of occasionally in medical literature.

It would appear true, indeed, that within the last quarter of a century physicians and surgeons have improved in the making of the diagnosis. And we of to-day are better diagnosticians in the aggregate than were doctors in those days, although it is affirmed that one of the world's most prominent physicians has recently said that his diagnosis was correct in only about sixty-two per cent. of his cases which came to the autopsy table.

It would, perhaps, be fair to say at the present time that there are many cases, both of a medical and surgical nature, in which our diagnosis must be somewhat limited. He who would serve his patient best must use all methods for correctly interpreting disease and other abnormal conditions of the body, not relying upon any one procedure to the exclusion of others which have proven to be meritorious.

The Course of Leprosy Infection.—H. Gougerot discusses first the "leprous chancre," following this with a description of leprous bacillemia. For many years the presence of the bacilli of Hansen has been noted in the large vessels. Still more often are the bacilli found in the small vessels and sometimes in the tissues and organs which appear to be healthy (microbic thromboses). The characteristic lesion of leprosy is formed at the point where these bacilli are arrested. By means of the great abundance of the bacilli, their agglomeration in masses, and the slight cellular reaction, this bacillemia of the acute attacks ought to be distinguished from all other types. This bacillemia is of short duration, lasting probably only during the first phase of the tegumentary attack and giving rise to general reactions, such as fever and so on. The chancre remains for a long time stationary and isolated. Slowly the second period develops and there may be ulceration, which is due almost always to a secondary infection or to repeated traumatisms. By insensible transitions the last period is reached. This might be called the tertiary period in comparison with the stages of syphilis. This last stage is characterized by localized or bacillary lesions, cutaneous or visceral.—*La Tribune Médicale.*

Pubiotomy.—Pfeilsticker describes the operation of pubiotomy as it is performed subcutaneously in Walcher's clinic. In distinction to all other operators, Walcher carries the needle that is to conduct the saw behind the bone from below upward, instead of from above downward. The proper point of the labium majus is selected and fixed with the index finger and the skin over it punctured with a scalpel to permit ready passage of the blunt needle. This is carried at first vertically down to the edge of the pubic ramus, so as to pass between it and the crus of the clitoris. The needle is then caused to hug the posterior aspect of the bone and is brought to the surface just above its upper surface. By operating in this way, the danger of hematoma and bleeding through injury of the corpora cavernosa of the clitoris is obviated. The author satisfied himself by experiments on the cadaver that the needle really did pass behind the bone in the manner indicated, and that, furthermore, its course was subperiostial, so that the bridge of periostium afforded a further protection to the soft parts from injury by the saw. Damage to the bladder is considered out of the question if the operation is performed in this way, and the after-treatment of the two minute wounds is of the simplest description.—*Zentralblatt für Gynäkologie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, May 12, 1906.

THE REVERSAL OF THE CIRCULATORY CURRENT.

AN announcement somewhat startling in character is contained in a recent paper by A. Carrel and C. C. Guthrie in the *Annals of Surgery* for February, 1906, in which it is claimed that the circulatory current in a limb may be successfully reversed by operative means, so that the red blood flows through the veins in a direction opposite to the normal venous circulation and the darker venous blood returns to the heart through the arteries. This, according to the writers, has been accomplished experimentally in dogs by cutting the main artery and vein of a limb and then uniting the central end of the artery to the peripheral end of the vein and the peripheral end of the artery to the central end of the vein. Thus, from a functional point of view at least, the artery becomes a vein and the vein an artery. These experiments are undertaken for the purpose of studying the changes which would take place in the member after reversal, and of possibly applying the method in a practical manner for the prevention of gangrene in cases in which the arteries are incapable of carrying the red blood to the capillaries.

Attempts of a similar character have been made before, but were never completely successful, and the results attained by Carrel and Guthrie are therefore of considerable interest. There are three physical obstacles which oppose the flow of the red blood through the veins in a direction the reverse of the normal, namely the valves, the numerous anastomosing branches which decrease the blood pressure by increasing the area of the cross section of the vessels, and lastly the resistance of the capillaries. Experiments made in living dogs, for the details of which reference must be made to the original paper, show, however, that these difficulties may be overcome, for, although the valves prevent at first a reversal of the current in the veins, they give way in a short time and the red blood flows through the veins as far as the capillaries, through which it also finally passes, and the arteries become filled with the darker venous blood. This circulatory phenomenon has been found to become established about three hours after operation—really a very brief period. A lateral anastomosis between an artery and a vein, without occluding the trunk of either vessel, was also made and it was found that a large volume of the red blood returned to the heart through the central end of the vein almost immediately. The peripheral portions of the vein and its collaterals were distended, but the valves were not forced and the red blood did not circulate through these vessels at first.

These experiments seem to show that the reversal of the circulation, in a dog's limb at least, is rendered possible by the establishment of an end-to-end arteriovenous anastomosis. Nothing has thus far been done, however, with reference to the permanent results of these operations, but these are promised and will be awaited with interest. If the procedure is to be applied as a surgical measure for the relief of gangrene in a limb where there has occurred an obliteration of the arteries, another factor enters into the calculation, namely the nutrition of the tissues of the member. Whether this can be carried on equally well by the blood, even if it flow in a direction the reverse of normal, should be made the basis of further experiments.

THE PATHOLOGY OF GENERAL PARALYSIS OF THE INSANE.

THE statement has been made that general paralysis of the insane is now on the increase, and this seems to be borne out by statistics. We know very little, however, of the etiology and pathogenesis of this disease. A growing dissatisfaction with the syphilitic hypothesis has become evident during recent years, although it still remains the favorite, and efforts are now being made to solve the problem from other points of view. Among these may be mentioned the researches made in the Scottish asylums for the insane, which are referred to in a recent article by W. F. Robertson in the *Edinburgh Medical Journal* for March, 1906. The writer alludes to the observations made by Bruce on temperature and leucocytosis, in which it was shown that in this class of cases febrile attacks occur every two or three weeks and that these attacks are accompanied by leucocytosis. In fact, in the third stage of the disease the leucocytosis may occur without any rise of temperature. He concluded from these observations that the general paralysis was due directly to poisoning by bacterial toxins, the absorption taking place through the gastric and intestinal mucous membrane. Other writers also came to the same conclusions, and Robertson, in conjunction with certain associates, commenced a bacteriological investigation relating to this point. They found that in cases of general paralysis a diphtheroid bacillus was particularly prominent in the mucous membrane of the gastrointestinal and respiratory tracts and that a similar organism could frequently be isolated from the brain. These findings seemed to confirm the idea of a chronic bacterial intoxication, and further experiments made in animals showed that certain symptoms resembling those of general paralysis followed the inoculation of cultures of the diphtheroid bacilli obtained from patients afflicted with this same disease. Robertson even goes further and states that a certain degree of immunity seems to be acquired by the paralytic against these bacilli, as the result of which he is able to combat them, notwithstanding the otherwise defective local and general powers of resistance. He claims also that the bacillus is conveyed from one individual to another by contagion, but if the mucous membrane of the organism is healthy, no further proliferation or invasion results. A preliminary weakening of the local and general defenses is evidently necessary, and of all the forces that can produce this condition there are three, according to the writer, which seem to

have special importance. These are the pathogenic agent of syphilis, alcohol, and nitrogenous foods used in excess. Local invasion of the bacilli through the intestine or the bronchi marks the beginning of a paralytic toxemia; this is manifested clinically by a "congestive attack," and at this time the bacilli are claimed to be found in great numbers in the blood stream in the neighborhood of the infective foci. In cases where the attack is repelled by the leucocytes, the clinical effect is a "remission," but in the end the defensive forces are overcome and then there is a fatal congestive attack.

Robertson states that there is evidence that the paralytic defends himself, and often with prolonged success, by manufacturing specific bacteriolytic antibodies. The suggestion seems opportune, therefore, that an attempt be made to produce such antibodies in lower animals and then to employ them as therapeutic agents. Such a method of treatment is to be given a trial in one of the Edinburgh asylums, and the results will be awaited with great interest by the profession.

THE TREATMENT OF RINGWORM IN SCHOOL CHILDREN.

Ringworm may be looked upon essentially as a school disease. Not only is it highly contagious, but likewise lingering and rebellious to treatment. It is serious in the sense that it frequently causes an interruption to education, and for this reason it should always be carefully and thoroughly treated when detected. A large number of "cures" for ringworm have been proposed, but their very multiplicity may be regarded in a way as an evidence of failure. The discovery that the disease was due to the growth of a microscopic fungus stimulated the search for a cure in a new direction, but even here success has been by no means complete. It is possible that further studies on the growth of this fungus on artificial culture media, may lead to the production of an antitoxin or other specific means of destroying ringworm when it has effected a lodgment on the human scalp. But thus far nothing definite has been accomplished in this line of endeavor.

Treatment of the disease may be roughly divided into direct and indirect. The former aims at destroying the fungus by the application of antiseptic drugs, the latter trusts to setting up an inflammatory reaction in the neighboring tissues. The great obstacle to a ready cure is undoubtedly the mechanical difficulty of reaching the fungus after it has penetrated the hair follicles, and of the many remedies proposed, including the *x*-rays, none has been uniformly successful. An interesting departure in the treatment of ringworm has been made recently by Dr. David Walch of London (*The Medical Press*). His method may be briefly defined as consisting of a procedure by which the scalp of the affected child is isolated instead of the child itself. In this way the latter is not prevented from attending school. Walch achieves this by encasing the shaved scalp with a film of collodion or other impervious substance. Thus protected, it is claimed that the child may go about without spreading the disease. Every week or ten days the film is peeled off and this effects a complete depilation. Before the film is applied, however, the scalp is thoroughly cleansed and a germicide applied, such as formalin or sulphurous acid. It is then exposed to the *x*-rays for about ten minutes, which aids in the depilatory process by loosening the hair bulbs.

There are many advantages claimed for the method, and among them is the shortening of the length of time required for treatment. It is advisable, however, that the procedure be conducted at a central station, if necessary to apply it to a large number of children, and this should be supplemented by a skilled and systematic school inspection. Without this aid it would be impossible to detect cases, to treat them properly, or to say when the disease is cured. The disease is largely prevalent among our own immigrant population, and its spread among the children of the public schools calls for thorough and decisive methods of treatment. The procedure recommended by the English writer seems as rational as it is simple, and certainly is deserving of trial.

A BLOW TO PHARMACEUTICAL REFORM.

It is a great pity that so excellent a cause as that of pharmaceutical reform should be so largely in the hands of intemperate and indiscreet advocates. The Medical Record has more than once pointed out the inexpediency, if not the injustice, of classing the manufacturers of proprietary remedies, even of those whose formulæ are secret, which are advertised solely to the medical profession, with the conscienceless makers of "patent medicines," so-called, which contain cocaine, alcohol, opium, or some other enslaving poison, and are sold to an ignorant public to its physical and moral ruin. But our protests have only called forth abusive comment from the noisiest and cheapest of the "reformers," who, wilfully or stupidly missing the point entirely, ask if both classes of preparatons are not "secret" nostrums, and seem to think that their interrogation is an unanswerable argument.

The Medical Record has repeatedly declared itself in favor of the publication of the formulæ of all proprietary remedies offered to the medical profession, but it recognizes that there are honest and honorable manufacturers of proprietary remedies who do not see the force of this contention, and it believes that persuasion is more effective than vituperation as a means of bringing them to a right way of thinking and acting. It has also hitherto given the reformers credit for honesty of purpose, but its faith has received a rude shock recently. In a letter published in a recent issue of the *Nashville Journal of Medicine and Surgery* by Mr. Hallberg, a member of the Council of Pharmacy and Chemistry of the American Medical Association, the editor is called sharply to account for a note in a previous issue of his journal. The offending matter was a quotation from a physician, who said: "I endorse worthy proprietaries, but I most heartily condemn the great tendency of the 'half-baked,' so-called manufacturing 'chemist' to foist upon the profession and public cheap imitations of standard preparations." To the casual reader this statement sounds orthodox enough, but it did not please Mr. Hallberg, who wrote (italics ours): "As a matter of fact the majority of the 'worthy proprietaries' are the products of physicians' prescriptions which have been appropriated usually by an ex-drummer or adver-

tising man, and rarely ever a medical man or even a druggist. These fellows who, through unlimited gall and self-assurance, have been exploiting the medical profession, often afterward turning to the public, are not even 'half-baked' chemists; they have never been near the fire at all; they pursue frenzied chemistry simply in pursuit of tainted money. *There is no established proprietary medicine that cannot be secured—as a rule far superior in quality—of the manufacturing pharmacists and chemists,* and instead of defending the manufacturers of specialties and charging the real manufacturing pharmacists and chemists with making cheap imitations of standard preparations, the physician should make it his business to find out that any preparations worth using can be had by [from?] the regularly established manufacturers, and, sometimes, also by [from?] retail pharmacists, *which are more true to the formula and composition than that made by those who originally exploited the article.*

This is a most astounding admission and one which we cannot believe would be endorsed by the *Journal of the American Medical Association* or by its Council on Pharmacy and Chemistry. If the object of persuading or coercing the manufacturers of proprietary remedies to reveal their formulæ is simply to enable the large manufacturing firms to make the same preparations and offer them to the profession with the prestige of a larger and longer-established house behind them, then the sooner the reformers reform the Council on Pharmacy and Chemistry out of existence the better. We cannot believe, however, that Mr. Hallberg speaks for the Council, and we hope to see a prompt official disavowal of his damaging utterance. If this is not speedily forthcoming, the Council will be discredited in the opinion of all honorable members of the profession who believe in "the square deal." No physician is compelled to prescribe a secret remedy against his will, but every one has a feeling for the under dog, and if it once becomes known that the agitation in favor of publicity is conducted in the interests of certain manufacturing chemists, the cause of pharmaceutical reform will be put back a quarter of a century.

Acute Nephritis and Chronic Tonsillar Hypertrophy.

Children with chronic tonsillar hypertrophy are apt to be the subject of a number of pathological conditions, and among them has been noted the appearance without evident exciting cause of an acute nephritis with its usual complement of symptoms—anasarca, albuminuria, casts in the urine, visual disturbances, and perhaps convulsions. Hougardy (*Le Scalpel,* 1905, No. 25) calls attention to the fact that in many of these cases an examination of the oral and buccal cavities will show the presence of chronically enlarged tonsils. Traces of recent infection are usually not in evidence, although the deep crypts may readily hide them. It may be noted in passing that an angina in such children often runs its course without being discovered. The writer reports six cases in which the association between the two conditions referred to was noted, and in one he was able to demonstrate conclusively the good effects of a tonsillectomy on the course of the nephritis. It seems appropriate, therefore, in the presence of the latter condition, to examine the throats of such children for the presence of hypertrophied tonsils, and as a precautionary measure to institute local prophylactic measures. As a final resort the question of operative interference may also be thought of. This observation merely constitutes another argument against leaving hypertrophied tonsils to be cared for by nature, as so many of the laity and some members of the profession itself believe it best to do. Their presence has been proved to be the cause of a number of conditions deleterious to the health of the child, and the possibility suggested by Hougardy is simply another link in the chain of condemnatory evidence.

The Seminal Secretion as a Source of Albuminuria.

Every physician has been frequently confronted with the puzzling occurrence of traces of albumin in the urine of patients in whom there is absolutely no sign of a renal affection. Some of these patients are young men, apparently in excellent health, who perhaps come to the practitioner because they happen to have been refused a life insurance policy. At first in such cases we are apt to suspect cyclic albuminuria, but a closer investigation, and especially a chemical study of the isolated proteids obtainable in these urines, show that in the majority of cases the albuminuria is due to an admixture of seminal fluid, or of minute amounts of secretion from the genital tract. A history of genitourinary infection or of disease or disturbance connected with the seminal apparatus will often be disclosed in these cases upon inquiry. While the suspicion of an admixture of seminal fluid has been expressed by more than one writer in commenting upon the albuminurias of healthy young men, a scientific proof of the origin of the proteid found in the urine in these cases was lacking until in a very recent article (*Russkiĭ Vrach,* No. 7, 1906) Slovtsoff reported that he was able to isolate from the urine of such persons an albumose similar to that which occurs in seminal fluid. For the precipitation of this peculiar proteid, Slovtsoff recommends a solution of sulphosalicylic acid, and notes that the precipitate so formed is soluble on the application of gentle heat. The discovery of spermatozoa in the urinary sediment would, of course, give a clue to the origin of the albuminuria, but unfortunately these elements are not always to be found in instances of this sort.

The Mode of Transmission of Leprosy.

The ability of the itch mite to serve as the medium of transport of the bacillus of leprosy from one person to another has apparently been demonstrated with sufficient thoroughness to render it an assured fact. In this connection the observations of Mugliston in Penang (Medical Record, August 26, 1905, page 343) and of Bassewitz (*Ibid.*, October 28, 1905, page 711) seem conclusive enough, and it has naturally occurred to leprologists to push the inquiry further and to try to saddle a similar responsibility on other insects. Until recently efforts in this direction have met with only indifferent success, but Dr. W. J. Goodhue, Medical Superintendent of the Leper Colony at Molokai, after several years of investigation feels convinced that both the bedbug and the mosquito *Culex pungens* can harbor in their bodies the bacillus of Hansen. Details in regard to the investigation and particularly as to the organs of the insects in which the parasites were detected are still lacking, and it must be remembered

that the mere demonstration of an organism in, say, the alimentary canal, of an insect feeding on the blood of infected persons does not *per se* justify the conclusion that inoculation is effected by this agency. If Dr. Goodhue can supply the links still missing in the chain of evidence, the prophylaxis of leprosy will at a single stroke be greatly simplified.

News of the Week.

Professor Alfred Dührssen of Berlin will be the guest of the German Medical Society at its meeting on May 15, in the hall of the Academy of Medicine. He will read a paper on "Modern Problems in Obstetrics and Gynecology." The discussion will be in both German and English, as Prof. Dührssen speaks our tongue well.

Monument to Dr. Skene.—At the unveiling of the memorial bust of the late Dr. Alexander J. C. Skene in Brooklyn on May 5, an address on Skene's life was delivered by Dr. A. Jacoby. The bust, which is of bronze, three times life size, is the work of J. Massey Rhind, and was erected by private subscription under the auspices of the Skene Monument Association. It is placed on one of the mounds west of the plaza at the main entrance to Prospect Park, Brooklyn.

Health Department Boat Tested.—The new ferry boat, *Riverside,* of the Health Department was tested for seaworthiness, etc., in a four-mile run on May 3, and found satisfactory.

Gasoline in the Sewers.—The Board of Aldermen on May 1 unanimously passed an ordinance forbidding the turning of explosive gases or liquids, such as gasoline waste, into the sewers. and imposing a fine of $50 for violation of its provisions.

Meningitis on an Italian Liner.—The Italian steamship *Il Piemonte,* from Naples and Palermo, was detained at quarantine owing to the occurrence on board during the voyage of nine cases of what turned out to be cerebrospinal meningitis. Three of the patients died on board and were buried at sea. Those still ill were removed to Swinburne Island for treatment.

For More Parks.—The Board of Estimate on May 4 authorized the issue of $1,749,930 bonds for park improvements. Of this amount, Manhattan and Richmond will get $649,000, Brooklyn and Queens $694,930, and the Bronx $406,000. While these allowances are much smaller than the sums asked for by the Park Commissioners, it is stated that it is the intention of the Board of Estimate to spend between $3,000,000 and $4,000,000 for opening new small parks and playgrounds in addition to meeting the cost of extending Riverside Drive, which is estimated at $5,000,000, and will be provided for by a special appropriation.

Changes of Address.—Dr. W. B. Pritchard of this city has removed to 142 West 72d street. Dr. J. H. Pryor has returned to Buffalo and will reside at 26 Linwood avenue. Dr. S. Henry Dessau of New Rochelle has removed to 156 Meadow Lane. Dr. Alexander Spingarn of Brooklyn, N. Y., has removed to 623 Willoughby avenue.

The Stevens Patent Medicine Bill.—The defeat of the Stevens-Wainwright bill, compelling the nostrum makers to print some information concerning the composition of their products on the labels of the bottles was effected on May 3, apparently more through the intervention of those in favor of such legislation than through the machinations of its opponents. By the addition of amendments not materially altering the spirit of the measure but tending to make it somewhat less sweeping in its provisions, the fate of the bill was sealed owing to the necessity for reprinting.

Lectures on Hydrotherapy.—A letter from Dr. William H. King, dean of the New York Homeopathic Medical College, in regard to the announcement in the MEDICAL RECORD of April 28, 1906, relating to a course of lectures on hydrotherapy to be delivered at Columbia University, states that lectures on this subject have been given for several years at the former institution by Dr. W. H. Dieffenbach.

The Smoke Nuisance.—The Health Commissioner's efforts to suppress the smoke nuisance in this city have begun to bear fruit. Nineteen cases for violation of the smoke ordinance are awaiting trial in the Court of Special Sessions, and one man, the chief engineer of the Edison Company, has been found guilty. Sentence is deferred until May 21. The maximum penalty is a fine of $500, or imprisonment for one year. Most of those arrested for smoke ordinance violations have pleaded not guilty, but in one instance the proprietors of a soap factory pleaded guilty and asked for clemency on the ground that a smoke consumer had been installed, so that the nuisance no longer existed. Decision was reserved and the case postponed.

Jewish Hospital for Deformities and Joint Diseases.—The board of directors of this institution on May 6 took possession of their new building at 1917 Madison avenue. The hospital was incorporated last October and it is stated that it will be a non-sectarian institution. It is expected that the hospital will be ready for the reception of patients before the end of June. The medical director is Dr. Henry W. Frauenthal.

Transfer of the Newberry Medical Library.—Arrangements have been completed for the transfer of the medical department of the Newberry Library, including the Senn Collection, to the ownership and management of the John Crerar Library. The collection cannot be accommodated in the temporary quarters of the John Crerar Library, so it will remain in its present location until a permanent building is completed.

New Hospital for Ravenswood, Ill.—The trustees of Ravenswood Hospital recently purchased a tract of land at Winchester and Wilson avenues, 192 by 152 feet, on which it is said a modern hospital will be erected.

Illinois Training School for Nurses.—The silver anniversary of the founding of the Illinois Training School for Nurses was celebrated recently in the Fine Arts Building. Ten members of the first graduating class and nine members of the first Board of Managers were present. In the twenty-five years the training school has been in existence, 825 women have taken the course. The alumnæ of the school have under consideration plans for building a home to be modeled in the main after the one in connection with Bellevue Hospital, New York. It will include living rooms, rest and recreation rooms, and a café. The cost will be approximately $50,000. Several tentative offers of aid have been made by wealthy men and women who are interested in the work.

A Fossilizing Climate.—The official report of Dr. T. L. Magee, the health officer of San Diego,

Cal., for the month of March, seems to confirm the claims made for the healthfulness of that city. Although an epidemic of measles had prevailed among the children during that month and the one preceding it, the average age of the decedents was sixty-four years. There were in all sixty-seven deaths, or 11.1 per thousand of population per annum. Nearly one hundred cases of measles had been reported, without a death directly attributable to the disease. There was one death from bronchitis and two from pneumonia in children. Only nine persons died under the age of thirty years.

San Francisco Institutions.—The reports from San Francisco state that while most of the private hospitals and some of the downtown institutions of larger size were destroyed by the fire which followed the earthquake, many others escaped. The Cooper Medical College and the Lane Hospital connected with it were only slightly damaged and escaped from the fire. The medical department of the University of California and the Children's Hospital were not seriously damaged.

Typhoid Fever at San Francisco.—A dispatch to the *Evening Sun* from Oakland states that there is no doubt that typhoid fever has broken out in the refugee camp at the Presidio, though the actual number of cases is uncertain. Something like twenty cases are believed to have been noted, though there is so much intestinal trouble from one cause or another that it is not possible to arrive at a positive diagnosis without more careful tests than it has been practicable yet to make.

Association of American Physicians.—The twenty-first annual meeting of this association will be held in the New Willard Hotel, Washington, D. C., May 15 and 16, 1906. The president and the council request that an oral abstract of each paper, prepared beforehand, to facilitate its delivery, be alone presented at the meeting. It is intended that, hereafter, no paper shall be read in full before the association.

National Association for the Prevention of Tuberculosis.—This society will hold its second annual meeting at Washington, D. C., in the New Willard Hotel, May 16 to 18, 1906. The secretary is Dr. Henry Barton Jacobs, 11 Mt. Vernon Place, West, Baltimore, Md., and the executive secretary is Mr. Livingston Farrand, United Charities Building, 105 East Twenty-second Street, New York.

American Gynecological Society.—The thirty-first annual meeting of this society will be held at Hot Springs, Va., on May 22-24, 1906, under the presidency of Dr. Richard B. Maury. There are thirty-four titles on the program, and a number of entertainments are promised. All desired information regarding the meeting, to which the profession in general is invited, may be obtained from the secretary, Dr. J. Riddle Goffe, 28 West Forty-sixth Street, New York City.

Quarantine Regulations.—The quarantine season for coasting vessels from parts south of Cape Henlopen began on May 1, 1906. The Sanitary Board of Havana has recommended that a quarantine be established against all the Gulf ports of the United States except Key West, Tampa, and Pensacola, on the ground that they have not accepted the regulations of the United States Marine Hospital Service.

Berkshire (Mass.) District Medical Society.—At the annual meeting of this society, held in Pittsfield on April 26, these officers were elected: *President,* Dr. A. B. Withington of Pittsfield; *Vice-President,* Dr. G. L. Rice of North Adams; *Recording Secretary,* Dr. I. S. F. Dodd of Pittsfield; *Treasurer,* Dr. Paddock of Pittsfield.

The Polk County (Ark.) Medical Society has been organized with these officers: *President,* Dr. W. P. Parks; *Vice-President,* Dr. P. R. Watkins; *Secretary,* Dr. C. C. Gunnels; *Treasurer,* Dr. G. P. Dunman.

Wholesale Vaccination in Philadelphia.—As the result of the occurrence of two cases of smallpox in the negro and Italian quarters of Philadelphia, a district of forty-five squares was quarantined for a number of hours on May 6 and during this time about 20,000 people were examined and 4,000 of them vaccinated. The work required the services of 500 policemen and fifty physicians.

Arizona State Medical Association.—The next meeting of this society will be held in Bisbee. The following officers were elected at the recent annual meeting at Phœnix: *President,* Dr. O. E. Plath; *Vice-Presidents,* Dr. W. V. Whitmore and Dr. A. C. Hickland; *Secretary,* Dr. E. N. Looney; *Treasurer,* Dr. R. F. Palmer.

Texas State Medical Association.—This association at its annual meeting held at Fort Worth on April 26, elected these officers: *President,* Dr. G. B. Foscue of Waco; *Vice-Presidents,* Drs. F. P. Miller, S. Wier, and A. B. Small; *Secretary,* Dr. I. C. Chase; *Treasurer,* Dr. R. F. Miller; the latter two being reelections. Mineral Wells was selected as the place for the next meeting.

Behring's Tuberculosis "Cure."—Consul-General Thackara of Boston reports that he has interrogated Prof. v. Behring regarding the latter's serum remedy for tuberculosis, and has been informed that he is not in a position at this time to furnish his preparation for the treatment of human beings until the experiments which he is now making on animals have been completely terminated, which will probably be not until the end of the present year. The date originally set for the giving of the discovery to the profession was August, 1906.

Short Skirts in Germany.—Some time ago the Police Department of Nordhausen, a city of Prussian Saxony, issued ordinances forbidding women whose dress skirts touched the ground to walk on the main square of the city or the adjacent streets. The measure has now been extended so that it covers all parts of the city, and to appear on any street with a trailing skirt renders the wearer liable to a fine of $7.50. It is stated in the text of the ordinance that it is "for the protection of health and for the prevention of tainting the air with dust."

National Association U. S. Pension Examining Surgeons.—The annual convention of this association, which now has a membership of more than six hundred, will be held at the New American Hotel, in Boston, Mass., on Monday and Tuesday, June 4 and 5, beginning at 10 o'clock on Monday morning. The secretary of the association is Dr. Porter Farley, Rochester, N. Y.

The "Journal of Abnormal Pyschology."—The first number of this bimonthly publication promises well for its future. The journal is meant to bridge the gap between medicine and psychology, and is primarily intended for the publication of articles embodying clinical and laboratory researches in abnormal mental phenomena as well as observations in the field of psychiatry proper.

Dr. Morton Prince is editor, and his associates are Drs. Hugo Münsterberg, James J. Putnam, August Hoch, Boris Sidis, Charles L. Dana, and Adolf Meyer.

A Lecture on the Medical Conduct of the Russo-Japanese War will be given at the Post-Graduate Medical School on Friday, May 18, at 8.30 P.M., by Captain Charles Lynch, Surgeon U. S. A., late medical attaché with the Japanese forces in Manchuria.

Action Against the Drug Trust.—Attorney-General Moody has made public a statement announcing that the government has filed in the Indiana United States Circuit Court a petition for an injunction against what is commonly known as the drug trust of the United States. The defendants named in the bill, it is alleged, have voluntarily combined together to control the prices at which proprietary medicines and drugs shall be sold to the consumer through the retail druggists, in violation of the Sherman anti-trust law. The parties to the combination include the Proprietary Association of America, the National Wholesale Druggists' Association, and the National Association of Druggists.

Obituary Notes.— Dr. ADRIAN D. WILLIAMS of Brooklyn died on May 4, at the age of thirty years. He served as army surgeon during the Spanish-American War and also in the Philippines.

Dr. WILLIAM J. FARLEY of Dallas, Ore., died on April 23, of heart disease, from which he had suffered for a number of years. He was a native of Pope County and was fifty-five years of age. He was graduated from Willamette University.

Dr. JOHN C. PEGRAM, JR., of Providence, R. I., died on April 26, in Brookline, Mass., at the age of thirty-four years. He was graduated from Brown University in 1892, and received his medical degree from Harvard University. At the time of his death he was visiting surgeon at the Rhode Island Hospital.

Dr. SAMPSON POPE of Newberry, S. C., died suddenly on April 22, at the age of seventy years. Dr. Pope took an active part in the redemption of South Carolina in 1876, and served for a number of years in the Legislature. He served in the Confederate Army through the entire war, and had practised medicine in Newberry since that time.

Dr. JOHN M. LAWSON of Union, S. C., died of pneumonia on April 24. He was graduated from the South Carolina Medical College and practised in Union, S. C., until the outbreak of the Spanish-American War, when he was appointed assistant surgeon in the army and served through the war.

Dr. CHARLES L. FISKE of Greenfield, Mass., died on April 21, at the age of seventy-five years. He was graduated from the Cincinnati Medical College and had practised in Greenfield for many years.

Dr. T. G. HERRICK of Newport, N. H., died on April 23, at the age of thirty-one years. He was graduated from the Harvard Medical School in 1898, and practised for some years in Brockton, Mass., until compelled to give up work on account of ill health.

Dr. J. COPLIN STINSON of San Francisco, former Commissioner of Public Health, was killed by the collapse of the hotel in which he resided, on the morning of the great earthquake, April 18.

Dr. CHARLES F. TAGGART of Los Angeles was accidentally killed at San Francisco, Sunday, April 22. He was born at Sparta, Ill., in 1862. Dr. Taggart had gone to San Francisco to attend the meeting of the State Medical Society, and escaped injury in the accident which befell the city. In some manner, however, he dropped a revolver while dressing and was instantly killed.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SAN FRANCISCO—PARLIAMENTARY; VACCINATION, VIVISECTION, SALE OF POISONS—THE NORMAL SECRET TREATMENT—METRITIS—ABDOMINAL PREGNANCY—SIR T. BROWN'S SKULL—PROF. SIMPSON—FRIENDLY SOCIETIES' ALLIANCE AGAINST DOCTORS—INQUESTS—OBITUARY.

LONDON, April 20, 1906.

THE awful calamity at San Francisco has hung over all our thoughts like a pall since the news reached us yesterday morning. Not that we talk much of it; everyone mentions it and then with a sigh seems to relapse into silence or turn for relief to what demands instant attention, for the work of the world must be done, even under the shadow of such a catastrophe. Our hearts go out to our oversea brothers in their sorrow with a sympathy "too deep for words." It is a national calamity, for are we not of one blood? The one point on which I like to dwell is the magnificent courage and energy with which you rose to the occasion, determined to do what man could do for fellow-man—courage and energy worthy of the race.

Oppressed by this burden, the medical matters of the week seem too trivial to divert one's thoughts, but I will gather a few fragmentary items for you.

The report of the Jenner Society refers to the possibilities of parliamentary action in reference to vaccination. The Act of 1898 was confessedly a mere experiment and was only to be in force five years, but was prolonged for another year. It is clear, therefore, that some action ought to be taken during the present session. The Jenner Society's report suggests that the government cannot be supposed to shirk their responsibility by letting the act drop altogether, but considering the want of backbone they have already exhibited, I do not feel much confidence that they will rise to the occasion. Indeed the report in question admits that time for full discussion cannot be secured this session, and says it would be reasonable to keep the act alive for another year, with an explicit promise of legislation in 1907. The reluctance of the government to commit themselves may be judged from an answer to a question in the House as to whether teachers might be excused from being vaccinated. The Minister of Education replied that it had always been a condition of appointment, though in certain districts it had restricted the supply of candidates. He was not prepared to make a definite statement, but was considering the possibility of throwing the responsibility of relaxing the vaccination provisions on the local authorities. Is it not a lamentable want of backbone for the "strongest government of modern times" thus to think of shirking its responsibility? But this is not the only instance of pliability, which gives color to the opposition's statements that the Cabinet is hopelessly divided on numerous questions. It is announced that an inquiry into the working of the Experiments on Animals Act is also to be held and the anti-vacs are jubilant over the matter. The form the inquiry will take is not yet decided, but scientific investigators are satisfied that it can result only in proof that no case of abuse can be established, and an impartial report will serve to neutralize some of the reckless falsehoods circulated by agitators.

Yet another parliamentary incident looks like readiness to relax restrictive legislation at the bidding of any "interest."

The Poisons and Pharmacy Bill introduced by Lord Crewe proposes to authorize local authorities to license such persons as they please to deal in certain poisons, *e. g.* insecticides, weed killers, sheep dipping preparations. This, it is said, is on the demand of florists, nurserymen and farmers and, of course, it is supported by the manufacturers of such preparations. The slight inconvenience of a few persons who have not a registered chemist within a few doors is to be the excuse for encouraging every petty sundry shop to lay in a stock of poisons among their household requisites. There is a clause restricting somewhat the sale of mineral acids, but not limiting their distribution to pharmacists or registered chemists.

Mr. Punch has long been known to discourage quackery, and it is, therefore, somewhat disappointing to see the name of his new editor figuring among the promoters of a "Normal Treatment Association," founded to exploit a so-called cure for inebriety and for the drug habit. This wonderful "cure" is, of course, a secret as to its composition, and yet we are asked to believe that no pecuniary benefit is derived from its sale. Still the new association proposes to supply it at a reduced price! It is only in the nature of things that a clergyman should be a leading spirit in a society of the kind and should be ready to testify to the efficacy of a "cure" of the composition of which he knows nothing, just as so many clerics seem to think their training qualifies them to pronounce on scientific and medical questions. Accordingly the Rev. H. B. Chapman takes the

secretaryship of this new society for exploiting a quack medicine and is supported on the committee by church dignitaries, to wit, the Primate of Ireland, the Bishop of Southwark, the Bishop of Chichester, and Canon Scott Holland.

A goodly array certainly of clerical authority to set against medical science and observation! But though they are, perhaps, not likely to contribute much to our knowledge of inebriety or its cure, they should be qualified to investigate the truth of the reverend secretary's statement at a recent meeting, that he had tested the treatment on 230 patients, of whom 220 were cured!

Dr. A. W. Addinsell read a paper at the Obstetrical Society on the 4th inst., on "Infective Metritis," which he regarded as originating in the endometrium as an inflammatory process which extended into the muscular wall. There was a history of infection following childbirth, miscarriage, gonorrhea or local interference, but no gross lesion such as fibromata or malignant disease. Persistent, excessive, uncontrollable hemorrhage was the feature which determined hysterectomy. Three stages were described: In the first there was perivascular inflammation, small round-celled proliferation encroaching along the line of vessels and invading the intermuscular connective tissue; the proliferation also surrounding the deepest mucus glands in the muscle wall. The second stage was the condition described as "fibrosis" by Bland-Sutton, and "arteriosclerosis" by Palmer Findley. In the third stage the fibrous tissue had degenerated, there was increased vascularity, and it was difficult to make out any muscular tissue. After all remedies had failed hysterectomy had to be performed.

Dr. Blacker said several conditions gave rise to intractable hemorrhage. Presenility and childbearing had to be considered. He did not think it was proved that these cases were due to infection. He believed steaming of the uterus was a most valuable remedy and should always be tried before resorting to operation.

Dr. Griffith did not favor steaming, but he thought cases of intractable hemorhage so severe as to demand hysterectomy were very rare, except cases of cancer and fibroids.

Dr. Eden did not consider the changes inflammatory. There was great difficulty in interpreting histological details because no precise study had been made of the uterine tissues at the different stages of the fertile period of life.

An account was afterwards read by Dr. E. J. Maclean of a case of abdominal pregnancy in which the fetus was removed in February last, six months after spurious labor at term, the patient, aged 34, not having previously been pregnant. The peritoneal sac was completely shut off from that of the fetus and was not opened during the operation, since which the patient's general health has much improved.

The Governors of the Norfolk and Norwich Hospital have decided to return the skull of Sir Thomas Browne to the Church of St. Peter Mancroft. Sir Peter Eade says the skull was taken away when the tomb was being repaired, sixty or seventy years ago. Later it was deposited in the hospital museum, where it has remained many years. A cast of the skull is to be taken, placed in a cabinet, and presented to Professor Osler.

Professor W. J. Simpson, of King's College, has gone to Singapore to inquire into and report on its sanitary condition for the government.

The Friendly Societies' Medical Alliance, which describes itself as a defensive organization against what its members consider unfair attacks from medical men and medical councils, met at Cambridge, when an alderman welcomed the delegates on behalf of the corporation and told them working men had set an example to other classes in dealing with social problems. The tone adopted by the speakers may be judged by one, who said they must meet the attacks of the Medical Council and the efforts of medical men who were determined to smash their associations. So these workmen's clubs proclaim their determination to defeat any attempt of the doctors to combine. Truly combination is a fine weapon when one-sided.

It is many years since we have had so fine an Easter. Among the indications of this a soldier fell out in a march from Sydd to Dover on Saturday and died from heat-stroke the next morning. Good Friday achieved a record in London with sunshine all day and a temperature running up to 70° F.

At an inquest on Tuesday the Coroner said that during 1904 there were 3,327 suicides in England and Wales, 2,504 being males, giving a percentage of 22.65 per 100,000 of population in the case of males and 6.95 in that of females. He noted as a curious point that in 1904 there was a decrease in the number following on a continuous increase since 1858. There was a falling off between 1903 and 1904 of 161 cases.

Dr. Waldo, holding an inquest on a child who died from suffocation, said he had made a study of these cases for five years and concluded that much injustice had been done to mothers who were constantly said to overlay their infants when drunk. In no case had he found any evidence of this. It was overwork, not drink, which was the cause. The reason why so many of the cases occurred on the night of Saturday to Sunday was that the mother worked harder on Saturday and usually went to bed over-tired, and therefore slept heavily. He advocated the use of cots.

At an inquest on Saturday concerning the sudden death of a domestic servant, the doctor who had been called in said he found her dead on arriving, and at the postmortem he found she had suffered from heart disease and tight lacing, which had injured the liver. The Coroner, Dr. Waldo, asked if the effect of lacing was very marked. The reply was yes, the liver was forced in two, on which the Coroner said he had many cases of tight lacing, but this was very remarkable, for the pressure must have been very great to split the liver in two. Verdict, death from heart disease, rendered by pressure on the liver by corsets. One would like the doctor to have given an anatomical definition of "the liver forced in two."

Dr. Henry Alexander Gogarty, consulting physician to the Kent and Canterbury Hospital, died on Wednesday. He resigned the post of physician to the hospital in April, 1904, after nearly thirty years' service, and was naturally elected to the consulting office with heartiest thanks for his services to the institution and to the sick poor of the city and county. In younger days he was surgeon-major in the Rifle Brigade.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE PROPHYLAXIS OF TUBERCULOSIS—SERUM THERAPY IN TYPHOID FEVER—ANESTHESIA WITH SCOPOLAMINE, MORPHINE, AND CHLOROFORM—THE DIAGNOSIS OF UNILATERAL RENAL PYURIA—THE SURGICAL TREATMENT OF GALLSTONES—POSTOPERATIVE PULMONARY COMPLICATIONS—DEATH OF PROFESSOR COLIN.

PARIS, April 5, 1906.

THE discussion on the prophylaxis of tuberculosis has been continued at the Académie de Médecine, and nearly all the speakers have agreed on the necessity for greater accuracy in the medical statistics of tuberculosis. The question of the obligatory reporting of the disease and of the compulsory disinfection which it involves, is rather more complex. Two views are in evidence, the one, which is upheld by Prof. Landouzy, is to the effect that systematic disinfection must be enforced in connection with coughing and spitting tuberculous patients, which can be accomplished only through obligatory notification. The other side of the argument is taken by Chauffard, who believes that compulsory notification would involve complications of various sorts, and considers that notification and disinfection should be made obligatory only after deaths from tuberculosis. Robin points out the harrowing situation in which the poor tuberculous patient would find himself if reporting the disease were made compulsory. Such unfortunates would everywhere be treated as outcasts and be deprived of all opportunities for making a living.

Josias also addressed the Académie on the subject of serum therapy in typhoid fever. The speaker discussed the results which he had obtained in his service in the Hôpital Bretonneau during the past four years in the treatment of children with typhoid fever by means of the antityphoid serum furnished by Professor Chantemesse. Formerly he used cold baths exclusively, and the mortality was 10-12 per cent.; since the use of the serum had been begun in addition to the hydrotherapeutic measures the mortality had fallen to 3.8 per cent. in 200 cases. Very few complications had been observed and relapses also had been rare and of little severity. If, on the other hand, a comparison is made with the official figures of the typhoid mortality in the Hôpitaux d'Enfants de Paris, where serum therapy is not used, a mortality of 12.6 per cent. is found in 1,031 cases. Since his figures represent such a very low number of deaths, the mortality being two-thirds less than that of other hospitals, he expressed to the Académie the conclusions that the antityphoid serum of Chantemesse, properly used, is harmless, and that children having the disease who are treated from the beginning with the serum and with cold tubs have much better chances of recovery than are afforded by hydrotherapy alone.

Walther presented to the Société de Chirurgie a very interesting report on the observations of Psaltoff of Smyrna, relating to general anesthesia by means of the combination of scopolamine, morphine, and chloroform. Walther has employed this method with universal success and has used it in 326 cases. In twenty-one of these he used the scopolamine and morphine alone for uterine curettages, setting fractures, etc., without ever encountering the slightest complications. In the seventy-nine last cases the author one hour before the operation gave an injection of 0.001 of scopolamine, together with 0.01 of morphine. At present he uses only one-half this amount of scopolamine. He has

never observed the tendency to hemorrhage that has been reported when three injections were given before the anesthetization. No syncopal attacks have been encountered. The principal advantage of the scopolamine is that it diminishes the danger of syncope from chloroform by reducing the amount of the latter agent necessary to secure anesthesia. In particular he referred to cases in which the patients were corpulent, emphysematous, and had fatty hearts, in which he would never have dared to use chloroform alone, but in which he was able to operate without any trouble by means of the scopolamine morphine method. Since Walther uses the inhaler of Ricard for administering the anesthetic one might be tempted to suggest that these good results might be due to the apparatus rather than to the alkaloids. The author has stated, however, that the use of chloroform alone with the same inhaler is sometimes attended by complications which do not occur after the preliminary administration of the scopolamine morphine combination.

Hartmann has reported a case of unilateral, renal pyuria, diagnosticated by the endovesical separation of the urine from each kidney. This case, he said, was a good illustration of the necessity for not confining oneself only to the methods of the old school, but for employing, when the occasion offered, such procedures as the endovesical segregation of the urine from each ureter, which alone could clear up a doubtful diagnosis in some instances.

The subject of the surgical treatment of gallstones was discussed by Linossier before the Société Médicale des Hôpitaux. He considered three forms of the affection: latent cholelithiasis, which is frequent, but which does not require treatment, owing to the absence of symptoms. Cholelithiasis, with paroxysmal manifestations, or biliary colic. Medical treatment alone should be employed for biliary colic, if no evidence of infection is present, for the dangers of surgical intervention under these conditions are greater than those of the disease itself. Surgical treatment is indicated only in the face of some grave complication. Finally, cholelithiasis, with permanent symptoms, owing to infection of the biliary passages, and for this surgical aid is necessary, and should be promptly given. When a stone is present in the common duct, together with marked evidence of infection, the case must be regarded as a surgical emergency. Progressive aggravation of the symptoms in cases of gallstones, despite careful medical treatment, furnishes the indication for prompt operation.

Chantemesse described before the Société de l'Internat the results obtained by the use of his antityphoid serum. He stated that the serum certainly cut short the duration of the disease, and that the ordinary complications were rendered much less frequent. During five years he had used his serum regularly, both in private and in hospital practice, and had obtained very excellent results. The serum stimulates the lymphoid tissue and is intended to increase the defensive powers of the body.

Professor Le Dentu presented an interesting communication on the pulmonary complications following surgical operations. Such complications are observed on an average in from 4-8 per cent. of all cases, but the rate of morbidity is a very variable one. Five different types may be distinguished. First, tracheal bronchitis of mild degree, from which recovery is rapid. Second, stitch in the side, owing to a small area of congestion, which disappears quickly. Third, the acute type, in which the face in cyanotic, the sputum is abundant and purulent: there is marked asphyxia, the dyspnea is intense, and a fatal termination is often observed. Fourth, the form with remissions and relapses, and fifth, a slow, progressive type, in which both lungs are affected. Pulmonary involvement after operations is most often observed on the first to the fifth day, and is due usually to one of two causes, the anesthesia or infection. Accessory causes may be sought for in chilling, embolism, and in paralysis of the bronchial muscles; in addition, operations on the upper part of the thorax particularly predispose to pulmonary complications. The direct cause of pneumonia is usually the aspiration of mucus during the anesthesia. The difference between chloroform and ether in this respect is very great, and it appears that chloroform gives rise to twice as many complications as ether. Great care is necessary to avoid this possibility; the patients should be cared for and their wounds be dressed in such a manner as to avoid exposure to the cold, and the wards should be well warmed. The ether employed should be pure and only small amounts (150 grams) should be administered, and finally, care should be taken to secure antisepsis of the mouth and pharynx. The treatment of these conditions is that of all forms of pneumonia, an excellent means of relieving the congestion consisting in bleeding to the amount of 200 or 300 grams.

French medicine has suffered a great loss during this month in the death of Professor Colin, general medical inspector, and formerly president of the Académie de Médecine. Colin was at once an eminent military leader and an accomplished scientist. His contributions to medical literature are very numerous, one of the most important being his "Étude Clinique de Médecine Militaire." He was also well known for his "Traité des Fievres Intermittentes," and his "Traité des Fievres Epidemiques," in which he expressed the many observations he had made in the course of his military career and which gained for him the authority he attained in the Commission d'Hygiène du Département de la Seine, of which he was a member for several years.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

ROENTGEN-RAY TREATMENT OF LEPROSY—END OF THE CHOLERA VISITATION—SMALLPOX.

MANILA, P. I., March 21, 1906.

REFERRING to the two cases of leprosy which were successfully treated in Manila, with the *x*-ray, and which have been mentioned from time to time, the physician in charge of the San Lazaro Leper Hospital reports that both cases have relapsed, and that lepræ bacilli are again found in skin scrapings taken from the place at which lesions existed before. The question now arises as to whether these persons were reinfected from the outside, or whether some focus of leprosy within the patient again became active. It is quite possible that the two cases could have been reinfected from the outside, because they were kept at the San Lazaro Leper Hospital in the same quarters in which the regular leper inmates were kept. It was not deemed advisable to discharge them, because under those conditions the cases would have been lost sight of. At the same time it did not seem desirable to place them in clean quarters; so that on account of the lack of a suitable house, they were of necessity confined to the leper hospital. The theory of the cases being actually reinfected seems tenable, yet the recrudescence of the disease also appears to be highly probable. It is said that steps will be taken at once to settle this point. One of the patients remained well from June 6, 1905, until the first week in March, 1906, a period of about nine months. The case was examined microscopically at frequent intervals, but it was not until this latter date that any lepra bacilli could be detected. The other patient remained well from August 11, 1905, until about the middle of February. As soon as some necessary apparatus arrives from the United States the treatment will be resumed.

Manila has now been entirely free from cholera since February 21, and for several months before that no actual cases of cholera seemed to originate in the city; the cases that occurred were either contact cases or actual infections introduced from the provinces. From the beginning of the present outbreak, August 23, 1905, there have been 282 cases with 250 deaths in the city of Manila. In the provinces there have been 3,742 cases with 2,807 deaths. The disease still remains confined within a radius of not over sixty miles from Manila. Judging from its virulence, it appears remarkable that it has not spread further. The maritime quarantine which has been instituted has, so far, remained entirely effective. There seems to be considerable ground for the hope that has been expressed, that the disease will shortly be entirely eradicated. During the past two weeks the number of cases has been reduced from fifty and sixty per day to four or five per day.

Several weeks ago an outbreak occurred unexpectedly in the province of Laguna, in the town of Siniloan. A total of 141 cases, with 102 deaths, occurred within a period of about ten days. This town affords another instance of what may be accomplished with modern sanitary measures applied in a rational manner, even though the support of the population may not be as good as might be. The three physicians who were sent to Siniloan immediately commenced their work by having the stools thoroughly disinfected, dry earth closets installed, the people instructed to boil their drinking water, and the town mechanically cleansed. The result of this campaign was most remarkable. After two days had elapsed there was a steady decline in the number of cases. The first day there were eight, the second there were six, the next day there were three, and the fourth day there were no cases. The results obtained here have been the most satisfactory that have been recorded in the fight against cholera in the present outbreak.

There has been a gradual increase in the number of cases of smallpox in the various portions of the islands. Those provinces which have been thoroughly vaccinated have remained almost entirely free. A very good example of the efficacy of vaccination is afforded by two provinces that border upon Lake Laguna; one of them, Rizal, has been vaccinated and now reports only a few scattered cases, while the other province, La Laguna, which has not been vaccinated, has reported a great many cases. In the town

of Calamba alone there have been over 100 cases of smallpox within the past few weeks.

Old residents state that from time immemorial smallpox has made its appearance at about this season of the year, and continued until the commencement of the rainy season, which is about the middle of June. The ravages of the disease are reported as having been most terrible in character. In Manila it was almost a yearly custom to erect a large hospital to shelter those who were stricken. At the end of the season these buildings were burned.

As the vaccination of the inhabitants proceeds, epidemics are becoming less and less common, and also more mild in character. If the commission continues to make the necessary appropriations it will not be many more years before the Philippines are entirely free from smallpox.

Progress of Medical Science.

Boston Medical and Surgical Journal, May 3, 1906.

The Treatment of Joint Disease by Passive Congestion.—The technique advised by H. F. Hartwell consists in the application of two or three turns of an Esmarch bandage about the limb above the affected joint. It should be applied just firmly enough to constrict the thin-walled veins, but not enough to obstruct the arteries, or, if at all, only to a slight extent. The venous congestion thus induced extends not only through the superficial veins, but also to the deep ones. This is a condition which one can observe with a tourniquet which has been misapplied, when one sees increased hemorrhage from all the deep tissues, even the bone marrow. The marrow cannot be directly influenced by a constricting band on the surface, and it must be that the blood is thus seeking a way of return for itself in the wide channels there left open. The most marked effect of passive hyperemia is the lessening of pain in the affected joints, and there is a decided lessening of the infectious veins. No rule can be given in regard to the grade of joint tuberculosis which will react under congestion. Apparently advanced cases do well under this plan of treatment. Cases with well-advanced lung disease or with amyloid changes will do better with amputation. In acute or subacute inflammations the best results are obtained in gonorrheal joints, especially in those which tend to ankylosis or in which the inflammation leads to bad stiffness. Ten cases are detailed and several skiagrams accompany the papers.

The Influence of Dampness of Soil and Climate on the Diseases of Respiration.—According to H. J. Barnes, damp soil, if a factor in promoting respiratory diseases, must act through the changes it produces in the neighboring air. In warm or hot weather it may produce a fog. In winter there is so slight an evaporation from the soil as to cause no appreciable increase on the relative humidity. The rainfall, as indicative of a damp climate, is a worthless guide in the temperate zone, because a large precipitation may coincide with a low humidity and the reverse. Influenza occurs regardless of all seasonable or meteorological conditions. Tuberculosis can be contracted in dry as well as in damp climates. In general the conclusion to be drawn from the evidence at our command is that all the diseases of respiration are common enough, regardless of dry or damp soils, in hot or cold, moist or dry climates, at least to raise a doubt if these conditions have any influence whatsoever as a cause of the diseases of respiration; but that an excessively dry air, which nature nowhere provides, but which we create in winter by raising the temperature of air holding a very small volume of watery vapor, and thus lower the relative humidity to an extent sufficient to impair the resisting powers of the mucous membrane lining the respiratory tract, may be a factor in the increased prevalence of respiratory diseases in cold weather.

New York Medical Journal, April 28, 1906.

Clinical Examination of the Stools.—R. Weil notes that organic diseases manifest themselves either clearly or immediately by their products on the stools or indirectly by their effects on digestion. Clear evidence of disease is obtained from the presence of blood, pus, mucus, or enormous masses of epithelia, or from the absence or marked diminution of bile. In the same category may be placed gallstones, pancreatic calculi, enteroliths, parasites, and parastiic eggs. The significance of each of the foregoing products is considered from a clinical standpoint, and the tests for each are described. Functional diagnosis must take account of the motor activity of the gastroenteric tract, its chemism, and the causes of abnormal conditions. The author thinks that the test diet as laid down in German textbooks is entirely unadapted to American conditions. The diet he has adopted with success in a general hospital is as follows: Breakfast—oatmeal with milk and sugar, coffee with cream, one or two eggs; lunch—bouillon, one quarter pound of meat, mashed potatoes, toast with butter, and, as dessert, jelly, omelette, or ice cream; supper—two eggs, toast and butter, milk, and a dessert as at lunch. The diet provides ample nourishment and variety, includes all the necessary constituents in such form as to be easily identifiable in the feces, and the amounts given may be varied to suit the taste of the patient without producing a very marked alteration in the feces.

The Diagnosis of Affections Characterized by Abdominal Pain.—G. P. Laroque endeavors to present a classified list of the various affections characterized by abdominal pain, so grouping them as to facilitate an early diagnosis at the bedside. In a general way two main subdivisions can be recognized (1) the non-surgical, or at least the non-operative affections, and (2) the purely surgical conditions; that is, those positively calling for surgical judgment for their proper arrangement, and which may demand operative intervention. The lesions of the latter group are further subclassified according to their existence as collateral signs, the phenomena of shock and of local or general peritoneal irritation in the symptom complex. Furthermore, as of greater or less diagnostic significance a few groups have been arranged, based on certain inseparable, clinical, contributing etiological factors in a given case which may often aid in a diagnosis by methods of exclusion. The bulk of the paper consists of an elaboration of the scheme outlined above. Too many details are given for summary here, and the paper must be consulted in its original form by those interested. An elaborate bibliography is appended.

The Roentgen Treatment of Some Non-Malignant Superficial Lesions.—C. L. Leonard discusses his results along the lines indicated in the title of his paper. By superficial lesions he includes not only those of the skin, but of the subjacent glandular organs. So far as the effect on tuberculous processes is concerned, he declares that it has been realized chiefly in the treatment of tuberculous adenitis and the sinus resulting from curetting and drainage. The agent has also been used in goiter, two cases being cured while two others were greatly improved. Dermatoses in which the rays have given good results include sycosis, favus, ringworm, alopecia areata, and hypertrichosis. In lupus very satisfactory results have followed, and the method is superior to the Finsen method in that a cure can be obtained without any breaking down of the skin. Other chronic skin lesions yielding to the stimulating and alterative action of the rays are eczema, psoriasis, and acne. Psoriasis is quite obstinate, and the patient is more liable to relapses than with eczema. The immediate and radical results produced by this agent in cases of acne vulgaris show that although the disease may be dependent upon the health and general condition of the patient, it is a local condition, which will yield rapidly to the local stimulative and alterative action of the Roentgen rays. The rapidity with which changes take place and the freedom from scarring, even where deep-seated pustules are present, makes this the most efficient method of treating this very common and yet persistent form of disease. There are many other skin lesions in which this method of treatment has been employed with great efficiency and remarkable results. Keloid, though requiring a long series of treatments, yields eventually to treatment, and when it is considered that the growths are liable to break down and change through retrograde metamorphosis into malignant disease, as in a case recently under treatment and apparently cured, the necessity for early treatment will be realized.

Journal of the American Medical Association, May 5, 1906.

Regeneration of Lost Parts.—T. H. Morgan reviews the facts and theories regarding the regeneration of lost parts in certain animals and the failure to do so in others. The question, he says, is possibly of some practical importance, for if we could determine why man does not replace a lost arm or leg, we might, perhaps, go further and discover how artificially to bring about this process. Regeneration appears to him as only a phase of the general phenomenon of growth, and if this is the case, why, he asks, does an animal that has ceased to grow begin to regenerate rapidly when a part has been removed? If we turn the question around the other way and ask, why does an animal stop growing at a certain stage, we may attack the problem at closer quarters. It is evidently not because the cells

have lost the power of growth; their power in this direction seems unlimited, nor can it, as he shows, be entirely attributed to an equilibrium between food supply and consumption. The question seems to be one of inhibition, and he suggests, as a possible explanation of the cessation of growth, a definite response to a condition of mutual pressure or tension of the cells on each other. When this is reached growth stops, and when we alter the tension by removing a part it begins again. The facts of regeneration of lost parts in the vertebrates are given and the reason why it fails in mammals and in man are discussed. Morgan does not think this can be due to greater complication of structure or to any process of natural selection. He thinks it more probably due to the fact that different tissues have very different rates of regeneration. In the higher mammals the failure to regenerate is observed in cases in which cartilage begins to change to bone, and he thinks the main trouble is in the slowness of the bones to regenerate in time with the other tissues. He says: "If the tissues in man still possess the power to regenerate, may we not hope in time so to adjust their rate of regeneration that the replacement of a lost limb may be produced? I cannot but think that some day this may be accomplished."

Duodenal Ulcer.—J. H. Musser and E. Martin report a case of perforating duodenal ulcer which is of interest as regards the diagnosis of the pre-existing conditions. The patient was of a neurotic temperament and gastric neurosis was strongly suggested. Of course when the symptoms of peritonitis appeared the earlier symptoms assisted in the retrospective diagnosis of ulcer and its location. The surgical procedure was simple and successful after the diagnosis was made.

Fracture of the Superior Maxillary.—W. E. Hartshorn reports a case of fracture of the alveolar process of the right superior maxillary bone extending from the median line to and including the first right bicuspid. The patient did not seek surgical aid until ten days after the injury. The fragment was entirely separated and freely movable. The treatment was by means of an interdental splint of aluminum, which, after several trials, was applied and worn without discomfort, reduction being made under chloroform. The appliances used are illustrated.

Proprietary Medicines.—G. H. Simmons discusses some general considerations of this subject. He calls attention to the fact that proprietary medicines are generally mixtures controlled by copyright or trade names, and are often secret or semi-secret in character. He states that while there is no objection to proprietary preparations *per se* the commercializing of the literature relating to materia medica is against all true scientific spirit and is demoralizing to both pharmacy and medicine. He explains in detail the difference between "patent" and proprietary medicines. Dr. Simmons says that whatever is secret is suspicious, and states that secrecy and mystery are the bulwarks of quacks and charlatans. He declares that a physician not only has a right to know what he is giving his patient, but that he has no moral right to prescribe a preparation of which he does not know the exact composition. He refers to the need of legislation on this subject and to the necessity for examination of various medicines and foods. He discusses the reliability of manufacturers and the exaggerated statements made by some in regard to the articles manufactured by them.

The Problem of the Synthetic Compound.—J. Stieglitz states that the problem of the enormous increase of the new synthetics is one of the most serious before the profession. Admitting the commercial or mercenary reasons for their production, he holds that there is a service to be done to humanity and a rational, legitimate ideal to be attained. While the progress has been comparatively slight, consisting, for the most part, in the production of a few more or less useful antipyretics, some hypnotics, some modifications of alkaloids, and a few more advanced preparations, the chemical successes in other lines, such as in the manufacture of the anilin dyes, teach a lesson of patience and of hope for the future. The problem is a complex and important one, but he does not see why we should not attain even to the chemical preparation of those specific antitoxins which we now draw from animals, at some time in the future. The main point of his remarks, however, is that there is need of some scientific standard or measure for the impartial sifting of the good from the bad in these synthetics, of some institution, perhaps international, or some central bureau of critical disinterested review. The need of a check on the great manufacturing houses is illustrated by him by quotations of deceptive chemical nomenclature, though technically truthful, covering what are practically mixtures as rank as any of those recently exposed by the Council on Pharmacy and Chemistry of the American Medical Association.

The Lancet, April 21, 1906.

Vaccine Treatment in Surgery.—By this term H. M. Gray refers, roughly speaking, to the injection into the patient of quantities of the organisms (dead) which produce the disease. The various phases of tuberculosis have provided the most frequent test for determining the efficacy of the method. Gray has used Koch's tuberculin R. (T. R.) for the purpose named, and has employed it in cases of glands, joints, peritonitis, upper air passages, tenosynovitis, and genitourinary maladies, all of a tuberculous nature. His results have been on the whole gratifying. A series of cases is detailed under the respective headings above enumerated. He has at times found it advantageous to use other vaccines in conjunction with T. R. in mixed infection of tuberculous foci. Staphylococcus and streptococcus vaccines are pure in another class of diseases, viz., ulcerated cancers. He indicates the probable usefulness of gonococcus vaccine in chronic (only) gonorrheal infections, such as gleet, prostatitis, epididymitis, endometritis, salpingitis, etc. He does not believe that the estimation of the opsonic index is necessary for carrying such cases to a successful issue. It may be necessary for the investigator, but is not for the clinician in the majority of cases. The bacteriologist is an absolute necessity, however, for he is the one who must find out what particular organism is causing the disease and prepare the corresponding vaccine. The dose of T. R. used has been 1-900 of a milligram, and the injections have been repeated at intervals of from ten to fourteen days.

The Treatment of Malignant Endocarditis by the Rectal Administration of Antistreptococcus Serum.—N. Raw reports two successful cases. He attaches great value to the remedy in general in cases of purely streptococcal infection, but finds that the usual method of injecting the serum under the skin of the abdomen is objectionable. He has used it per rectum in 25 cases, and declares that he would not go back to the old method. His plan is as follows: The bowels are freely cleared by aperients and the rectum is gently washed out with a little warm saline solution. The formula for injection is as follows: Antistreptococcic serum, 20 c.c.; normal saline solution, 100° F., 40 c.c.; to be gently injected into the rectum morning and evening or as required. It is found that there is no pain or discomfort; the serum is rapidly absorbed and seems to exert the same bactericidal influence as when given under the skin; skin rashes are rarely seen and the thirst and dry tongue are relieved. When given in such a small amount there is no difficulty on the part of the patient in retaining it, and it is rapidly absorbed. In fact, he is satisfied beyond any doubt that equally good results are obtained by absorption of the serum per rectum as by subcutaneous injection and with, so far, no skin or joint complications. In addition to the two favorable cases a third and fatal case is recorded. The remedy was given per rectum in this instance also.

A New Method of Operating in Pannus.—The method described by W. Primrose consists in causing an extravasation of blood into the subconjunctival tissue around the cornea. By its mechanical pressure and by acting as an irritant foreign body setting up a local inflammation, it causes the obliteration of the vessels which vascularize the cornea. The point of a cataract knife is passed through the conjunctiva at a distance of two or three millimeters from the cornea, made to puncture one of the larger vessels, and is then withdrawn. The wound should be as small as possible and made obliquely by holding the knife at an acute angle with that part of the surface of the eyeball which is being operated on. In this way there is no external hemorrhage, but bleeding takes place into the subconjunctival tissues and is arrested automatically by the pressure of the extravasated blood upon the vessel walls. In like manner many of the smaller vessels in the vicinity are mechanically closed. This mechanical action is increased by the formation of a coagulum, the fibrinous part of which shrinks and makes the whole mass smaller. Extravasated blood acts as an irritant, probably chemical as well as mechanical, so a non-infective inflammation is set up which results in the absorption of the blood clot. This process acts as a counterirritant to the inflammation of the corneal tissues and so tends to remove the seat of inflammation and the supply of blood from the diseased cornea to the clot, where the effects of the inflammation are com-

paratively trivial. By the time the blood clot has disappeared the blood-vessels in the cornea affected by the operation have shriveled up and the cornea has regained much of its transparency. The whole pannus may be treated in this way at one time or the operation may be repeated from time to time, only a part of the pannus being treated each time. The latter is always advisable when the pannus is marked, as the inflammatory reaction is sometimes very severe and accompanied by a good deal of pain. Although the structures in the anterior part of the eyeball are all more or less affected by the inflammation, this is easily controlled and subsides in a few days with the application of suitable remedies.

British Medical Journal, April 21, 1906.

Antityphoid Serum Obtained from the Goat.—The general conculsions presented by A. Macfadyen from his experiments are summarized in the following statements. He has found that the intravenous injection of the goat with the toxic cell juices of the *Bacillus typhosus* in small and carefully regulated doses resulted in the production to a very considerable degree of an antiendotoxin—inasmuch as 1-50 c.c. of the serum neutralized thirty lethal doses of the typhoid endotoxin. This property did not exist in 3 c.c. of normal goat's serum. This titrate was obtained after about four months' immunization of a goat with the toxic cell juices, and is quantitatively much higher than that obtained by so competent an observer as Besredka, even after two years' immunization of a horse with dead and living typhoid bacilli. The serum acted when injected simultaneously but separately from the toxin; also when injected at the onset of toxic symptoms. Subcutaneous administration was also effective. The serum, in addition to antiendotoxic, possessed agglutinative and bacteriolytic properties. The serum, while neutralizing the typhoid, did not neutralize the cholera endotoxin, and was to this extent specific in its action. The method which has led to successful results on the goat will next be tested on the horse, in order to ascertain in how far it is feasible to obtain a corresponding rise in the immunizing value of its serum.

Exophthalmic Goiter.—One case is reported by H. T. Dufton, who makes the history the basis of some remarks on the nature of the disease, which he is inclined to regard as essentially one of the sympathetic nerve ganglia, rather than one of the glandular system. The ganglia connected with the cardiac plexus would give rise, if diseased, to an inhibition of function and to a loss of tone in the large arteries. This loss of tone, produced by disordered action of vasomotor nerves, would cause a general dilatation of the large arteries; it would be first felt on the right side and in the innominate artery, the first large vessel arising from the aorta; it would be followed in a direct line into the common carotid, the external carotid, and into the first branch of the external carotid—that is, the superior thyroid artery. Similarly the loss of tone producing dilatation in the thyroid axis would be continued into the inferior thyroid artery. This would account for the usual prior enlargement of the right lobe of the thyroid gland. The proximity of the middle cervical ganglion which gives off the middle cardiac nerve; the sympathetic nerves at the back of the sheathe of the common carotid artery; the upper and lower cervical ganglia with the internal carotid and subclavial arteries are to be remembered. According to the author, it seems reasonable to argue that the tachycardia, and possibly the palpitation, may be caused by communication from the last cervical ganglion, through the accelerator nerves, as it is well known that when stimulated these nerves produce a quickening of the heart's beat. It is well known, also, that division of the cervical sympathetic causes vascular dilatation of the face, which is accompanied by increased perspiration. As regards the exophthalmos, a similar argument will obtain from the contiguity of the sympathetic root of the lenticular ganglion with the ophthalmic artery. The persistent or enlarged thymus, the enlarged lymphatic glands, the increased connective tissue in the neck, are not these due simply to increased vascularization? The only actual evidence that the disease originates in these ganglia is based on the fact that Greenfield has found changes therein in the shape of leucocyte invasion and degeneration of the ganglion cells. It remains to be demonstrated that such changes are constant.

Pneumococcic Arthritis.—W. B. Secretan and W. Wrangham refer to Cave's tabulation of reports of this disease up to 1901 (31 cases) and have collected 25 additional cases since published. They find that the knee was the point involved in 15 out of this latter series of 25 cases. In most cases the arthropathy occurred a few days after the commencement of the lung trouble, but in some instances among children no pneumonia was present. In one a pneumococcic otitis media suppuration seems to have been the original focus of infection. The character of the fluid in the joints varies from turbid serum to thick pus. It may vary in different joints in the same individual. In the authors' opinion the thinner the pus the better the prognosis. If aspiration shows a pus-like fluid the joint must be opened and drained under an aseptic régime. Often the pneumococcus is the only organism found, but naturally the most disastrous results may follow invasion by other organisms. Finally the authors report one personal case in a lad of 16 years with involvement of one knee, the pus from which showed fine cultures of the pneumococcus. The joint was drained as above indicated and the boy made a good recovery. Six months later the movement in the joint was perfect.

Vasodilatation in Hemoptysis.—E. T. Smith reports a case of hemoptysis, his patient being a man of 52 years. The blood appeared to come from a ruptured atheromatous pulmonary vessel. He was treated by bleeding at the elbow and the free use of amyl nitrite. Later a mixture was given of sodium nitrate, nitroglycerine and epsom salts. The author quotes from various authorities as to the sources of hemoptysis in general. He decries against the use of adrenalin under these circumstances, although he finds that it has its advocates. If it be good in this connection (admitting that it constricts the arterioles generally and raises blood pressure), it cannot be for this latter, but for its former (constricting) effect. In this case it must be conceded that the pulmonary vessels are acted on by the same vasomotor mechanism as those of the systemic circulation, and synchronously with them. And furthermore, that the vessel-constricting power of the drug, as regards the pulmonary vessels, is strong enough to counterbalance the manifest disadvantage of its also admitted pressure-raising action. The author doubts, however, that such premises can be admitted.

Berliner klinische Wochenschrift, April 16, 1906.

The Value of Bottini's Operation.—Cohn says that while he does not seek to underestimate the dangers and disadvantages attending Bottini's operation, he considers that there are certain instances in which it can profitably be employed. Sometimes the operation is not followed by any improvement whatever, and in some cases relapses occur, but the operation is well adapted for use with patients who cannot be subjected to general anesthesia, or who are too feeble to be exposed to the risk attending a protracted convalescence. The author draws his conclusions from thirty cases treated according to this procedure out of 150 cases of prostatic hypertrophy which have been under his observation in the last three years. The earlier operations of the series were done under general anesthesia, and then recourse was had to local anesthesia, but the later operations were performed entirely without anesthesia. The possibility of doing this is considered by the author one of the greatest advantages of the method. He introduces a small amount of boric acid solution into the bladder, and controls the course of the incisor by a finger in the rectum. A permanent catheter is always introduced at the termination of the operation, and is removed on the fourth day. Disadvantages of the operation are the possibility of secondary hemorrhage, fever and chills, and pulmonary embolism. Two of the author's patients died, one of secondary hemorrhage and the other as the result of severe cystitis and pyelitis present before the operation. The result was perfect in some cases and partially successful in others.

Experimental Carcinoma Investigation.—Bashford criticises the observation published some time ago by Ehrlich and Apolant, who stated that in the course of a carcinoma transplantation experiment in mice a sarcoma developed. One of the explanations offered by them for this phenomenon was the possibility that connective tissue was transplanted together with the carcinoma cells, and that this in consequence of repeated passage through the animals developed an increased capacity for proliferation. Bashford considers that his experiments have demonstrated that the connective tissue inoculated always degenerates, and he suggests that in order to gain an insight into these problems systematic observations on an extremely large number of animals must be made. Thus, in one instance a tumor was transplanted into 390 mice, and five of the animals were killed at the expiration of two, four, eight, sixteen, twenty-four hours, two days, three days, etc., after the transplantation. The transplanted cells were then fixed

and prepared in serial sections covering the entire colony of foreign cells.

Münchener medizinische Wochenschrift, April 17, 1906.

Alcoholism in Munich.—Kraepelin contributes a very severe arraignment against alcohol and urges on members of the medical profession their responsibility in checking the consumption of spirituous beverages. Out of 1,373 patients treated in his psychiatric clinic during the year 1905, 253 men and 30 women were admitted for purely alcoholic psychoses, but the number of patients whose condition was due, in great measure, though not entirely, to the use of alcohol, was very much larger, so that Kraepelin estimates that alcohol not only directly causes about one-third of all mental diseases in men coming under observation in Munich, but also plays an important rôle in the causation of a whole series of severe mental disorders, of which general paralysis, epilepsy, and arteriosclerosis stand in the foreground. One of the most prominent factors which permits the existence of such a state of affairs consists in the ignorance of the people at large; and to combat this the physicians must exert themselves to a much greater degree than has heretofore been the case. Physicians should avoid prescribing alcohol as a beverage of any sort in private practice or in institutions, and public institutions for the treatment of alcoholism should be provided. If alcohol could be removed from the world to-day the number of patients with mental disorders would be reduced one half, while if adequate provision for the treatment of alcoholism should be made the number would be reduced by one-third.

A Remarkable Case of Tuberculosis of the Heart.—Knauth describes this case, in which the patient was a young man who for nearly a year suffered from a variety of symptoms, of which the most conspicuous were pallor, emaciation, night sweats, and enlargement of the heart. For nine months he was able to do his ordinary work as a household servant, when he manifested symptoms pointing to a general miliary tuberculosis with tuberculous meningitis. After an illness of about six weeks he succumbed, and on the autopsy it was found that the entire heart had apparently been transformed into a mass of pus. Closer examination revealed that almost the entire thickness of the cardiac musculature had been irregularly eroded by the degenerative process, so that only a very thin septum of muscle remained between the endocardium and the broken-down tissues. This condition had remained entirely unsuspected, as up to the time of death the pulse had been of excellent quality, and it was particularly remarkable that the man had been able to be up and about attending to his work during so long a period while this extensive destruction of cardiac tissue was going on.

Uremic Neuritis.—Dunger says that it has not been universally recognized that the disturbance of metabolism attending uremia may have as a consequence a typical neuritis. In illustration he cites a case of severe acute hemorrhagic nephritis occurring suddenly in a man of 27 who had previously been perfectly well. In a very short time high temperature, extensive edema, headache, insomnia, restlessness, very small quantity of urine, etc., developed. While these symptoms were slowly improving, very severe tearing pains developed in the left arm, the nerve trunks became very sensitive, and there was paresis of the entire arm. At the same time the left forearm remained edematous, while the edema was subsiding in other portions of the body. Finally all the local symptoms disappeared, except paretic manifestations in the domain of the median nerve. The author considers that the cause of such a nephritic neuritis is to be sought for in the altered composition of the blood and the loading of the blood with products of imperfect metabolism. The author suggests that neuritis is not as uncommon in nephritis as the absence of observations in this regard would appear to indicate, owing to the fact that the pains, numbness, etc., often complained of by such patients would, on detailed examination, be found referable to a neuritic condition.

Deutsche medizinische Wochenschrift, April 19, 1906.

The Participation of the Internal Ear in Injuries to the Head.—Rhese has studied the condition of the auditory function in a hundred cases of head injuries of many different sorts, and has found that in a very large number of instances, even if there is no impairment of hearing to be detected when the spoken or whispered voice is used as a test, very considerable abnormalities are to be discovered when more delicate means of investigation are employed. He believes that the internal ear participates in most cases of head injuries accompanied by concussion, and says that examination made immediately after the accident shows a constantly recurring symptom complex, comprising: nystagmus; interference with bone conduction; shortening of the duration of perception for the entire range of tones; irregularities in the perception of the different tones; simultaneous affection of both ears; a very marked reduction in the audibility of the watch tick, which is in contrast to the audibility of the voice; easy fatigue for tuning fork tones; positive Rinne's test; marked dilatation of the vessels along the roof of the auditory canal. When this syndrome occurs, to some extent at least, the suspicion of a head injury is justifiable.

Observations on a Meningococcus Serum.—Kolle and Wassermann describe the rather intricate steps which led to the production of an antimeningococcus serum as well as an elaboration of a method for testing it. The serum is obtained from horses, and not only has specific agglutinating properties, but, the authors believe, should also be of value both for protective inoculation as a prophylactic measure as well as for therapeutic purposes in those already infected. The authors consider that the product has been sufficiently perfected to render its application advisable, and recommend observations with it in cases of the disease. While the exact dosage can be determined only by experiment, they consider that subcutaneous injections of 10 c.c. would be entirely harmless and yet of therapeutic value.

The Roentgen-Ray Treatment of Leukemia.—Flesch sums up his position in regard to the *x*-ray treatment of leukemia by saying that although he does not wish entirely to discountenance this plan of procedure, he does not consider it wise to be too sanguine in regard to the results obtainable in this way. It is undoubtedly possible to affect myelogenous leukemia favorably and to make the patient more comfortable, but more than a temporary improvement is hardly to be expected. In lymphatic leukemia the value of radiotherapy seems still smaller, though the reason for this lack of efficacy is still unknown. A much wider range of experience will be necessary before the question can be settled, and it appears not improbable that protracted radiation may in some cases lead to insufficiency of the hematopoietic organs.

American Journal of the Medical Sciences, February, 1906.

On the Extermination of the Mosquito.—A. H. Doty declares that the evidence must now be considered conclusive that yellow fever is transmited by the variety of mosquito known as the *stegomyia*. All varieties of the mosquito propagate only in water. With the exception of the *sollicitans*, all mosquitoes deposit their eggs on the surface of the water. *Culex sollicitans* will breed in no place other than salt water. The mosquito lives for some time. As to the treatment of baggage coming from yellow fever ports, the writer believes that this is unnecessary, provided the period of transit exceeds two days. All varieties of the mosquito cannot be exterminated by the same means. In the case of the *sollicitans*, it is only by the proper drainage of salt water swamp lands along the coast that its propagation can be prevented. If accumulations of surface water are prevented by drainage, propagation ceases. Cisterns and rain-barrels contribute largely toward the propagation of *Culex pungens*. The extermination of this variety, as well as of *Anopheles* and *Stegomyia*, depends largely upon the efforts which are made to prevent the propagation in receptacles about the premises. Draining and filling in of ground depressions is also important. If ground depressions cannot be drained or filled in, petroleum oil may be used as a temporary measure. Bad drainage and the accumulation of fluid filth furnishes the breeding place for the *stegomyia*.

Cystinuria.—W. McKim Marriott and Charles G. L. Wolf give a careful review of their work. The patient from whom the urine was taken was a woman sixty-five years old. She was a surgical patient, the left breast being removed for carcinoma. The right breast had been excised for carcinoma fifteen years ago. The writers give a table showing the result of their analyses of the urine. The amount of undetermined nitrogen varied from seven to ten per cent. The addition of the amino-acid nitrogen brought this up to twelve and nine-tenths to fifteen and five-tenths per cent. To what this large amount of undetermined nitrogen is due the writers are unable to state. It is without doubt made up in great part of the amino acids, the diamino acids, or the diamins. A very large amount of neutral sulphur is formed at the expense of the alkaline sulphates. The ethereal sulphates remain at the same level. Cystinuria

is apparently not accompanied by any changes which lead to disturbances other than the cystinuria itself. A cystin calculus examined some time ago by one of the writers consisted exclusively of hexagonal cystin. The cystin in this case on recrystallization consisted exclusively of six-sided plates.

The Present Status of Blood Cryoscopy in Determining the Functional Activity of the Kidneys.—Edwin Beer tells us that cryoscopic data like quantitative analysis of the urine, indicate in a measure what is happening at the moment and nothing more. The compensatory powers of the kidney cannot be observed and probably they will never be revealed. These organs, though the most important in regulating the molecular concentration and osmotic pressure of the blood, are not the only ones concerned in this process. An almost normal kidney may be so disturbed in its functional activity as to appear seriously diseased. The concentration of the blood may be normal, even though the kidneys may be very badly diseased. The concentration of the blood may be above normal, contraindicating any removal of kidney tissue even though the second kidney is normal anatomically but is suffering from a functional disturbance due to nervous reflexes or to toxins from the other diseased kidney. Even though both kidneys are in good condition, the concentration of the blood may be markedly increased. With normal concentration and bilateral disease, nephrectomy may remove most of the functioning tissue of the kidneys and so bring on uremia and death. The list of cases that have survived a nephrectomy despite high molecular concentration is steadily growing. Patients with normal freezing point do not necessarily survive the operation. The investigators have not yet been able to decide which cases of high concentration are not of renal origin or which cases of low concentration are suffering or are likely to suffer from renal insufficiency.

Operations for Relief of Pelvic Diseases of Insane Women.—Leroy Broun classifies the pelvic operations on insane women as follows: major operations, which include all abdominal sections; operations for displaced uteri, which include also, when present, a repair of cervical and perineal injuries; and minor operations, including a restoration of injuries of the vagina and cervix and uterine endometrium. As a result of all the operations done (242), 112 patients have been physically benefited in a large degree; 107 have been noticeably improved. The beneficial effect of surgical relief finally ending in a mental recovery is confined in the writer's experience to those patients whose mental disturbance would be largely influenced by the presence of pathological conditions. He attempted to preserve one or both ovaries if consistent with the physical welfare of the patient. It was necessary to remove both adnexa in twenty-three instances. Of the seven abdominal sections in which the mental recovery of the patient was largely brought about as the result of the operation, the adnexa were removed in only two. Uterine hemorrhages are known to aggravate the mental state of insane patients. Surgical operations upon insane patients do not meet with the difficulties that are often considered to exist.

Researches on the Blood of Epileptics.—B. Onuf and Horace Lograsso give as the principal fact that has been brought out by their investigations, the great fluctuation of the leucocyte count. In the first four days the leucocyte count showed slight fluctuations. The examinations were interrupted for a few weeks, but after being taken up again the leucocyte curve ran very evenly for about a week, when a distinct rise occurred. Within several days the patient had a seizure. An examination on the next day gave the highest leucocyte count so far obtained. The curve suggests that in the intervening days the count was still higher. The curve tends to show that where the intervals between the seizures are long, fluctuations of leucocyte count are apt to be slight and to concentrate around the period of seizures and that the curve is apt to be an almost entirely even one in most of the time of the free interval.

Complete Amputation of the Thigh, with Replantation.—Alexis Carrel and C. C. Guthrie have performed five experiments on dogs. The first four were made for the purpose of developing an operative technique. The failure of the last operation was due only to a fault of technique. Notwithstanding the fact that it was unsuccessful, it gives important information in relation to the replantation of a limb. The circulation was easily and entirely re-established through the replanted thigh. The pulsations of the femoral, popliteal, and posterior tibial arteries were as strong as the pulsations of the corresponding arteries of the other side. The capillary circulation was exaggerated. The greatest departure from normal observed in the character of the circulation of the replanted limb was the dilatation of the smaller vessels. At present it is impossible to foresee the changes that may occur in the nutrition of a replanted limb. The writers are going to pursue their investigations further.

Tetany: A Report of Nine Cases.—Campbell P. Howard declares that in the treatment of tetany the first indication is to correct the predisposing condition, such as diarrhea, and so on. The stagnation of the stomach contents and further absorption of the toxic substances are relieved by the operations of pyloroplasty and gastrojejunostomy. Thyroid extract is indicated in the tetany of pregnancy and in any cases associated with thyroid deficiency. Finally, for the spasms, absolute rest in bed, cold to the spine, baths, packs, bromides, and so on, have given little or no result. Chloroform administered to the point of primary anesthesia may lessen the severity of the spasm.

French and Italian Journals.

Pernicious Anemia Successfully Treated by Radiotherapy and Antitoxic Serum Injections.—Louis Rénon and Léon Tixier have studied in a patient with pernicious anemia successively the effects of arsenical medication, treatment by radiotherapy, and that by injections of antitoxic serum. Arsenical treatment, which gives excellent results in many cases, does not constitute a specific treatment for pernicious anemia. On the contrary, blood regeneration resulted from the employment of the *x*-rays alone or in combination with injections of antidiphtheritic serum. The authors insist less on the clinical cure since such ameliorations are often transient, than on the hematological determinations of blood regeneration under the influence of physical and clinical agents which were used in this case. Blood examinations practised during the hours which followed treatment by irrigation and antitoxic injections showed that the stimulation of the hematopoietic organs was attended by a very notable increase in the number of red blood corpuscles, by an eosinophilia as remarkable for its constancy as its intensity, and finally by the presence in the blood of polychromatophiles, young elements of bone marrow.—*Le Bulletin Médical,* March 14, 1906.

Hysterical Manifestations by Imitation.—Terrien speaks of various hysterical manifestations of great interest. A child became paralyzed in both legs after an attack of diphtheria. The writer treated this little patient daily by means of electricity. At the time of his visits he examined the throats of all the other children in the house. One morning one of the small brothers, eleven years old, walked slowly into the room dragging his leg. The mother informed the writer that this child was also paralyzed. On inquiry it was found that the boy had never had the slightest signs of diphtheria. He was imitating the paralysis of his brother. Several other children imitated the more apparent manifestations of coxalgia from which a playmate was suffering. Another hysterical manifestation described by the writer was that of Cheyne-Stokes respiration. The writer then emphasizes the hysterical manifestations of appendicitis, relating a case in which operation was performed. The appendix was perfectly normal. He calls attention to the fact that as far as possible the discussion of diseases with their description should be avoided in the presence of hysterical individuals.—*Le Progrès Médical,* March 10, 1906.

The Leucocyte Formulæ of the Early Period of Pulmonary Tuberculosis and of Articular Tuberculosis.—V. Giudiceandrea, E. Felice, and A. Saporiti have studied the leucocyte reaction of the blood in early pulmonary and in articular tuberculosis. In the pulmonary form the most common leucocyte formula in early stages may be summed up thus: Total number of leucocytes normal; slight neutrophile polymorphonucleosis; diminution of total number of lymphocytes with increase in number of small lymphocytes. Eosinophilia corresponds with what has been observed after injections of tuberculin. The leucocyte formula as a symptom gives probability to the diagnosis of pulmonary tuberculosis. In the articular form of tuberculosis in the early stages the formula is the same as in early pulmonary infection. Lymphocytosis is the exponent of advanced tubercular processes; neutrophile polymorphonucleosis indicates advanced secondary infection. Small lymphocytes indicate a closed focus of disease. The diagnostic value of these signs will increase when we know the lymphocyte formula of other forms of articular disease. Eosinophilia enables us to judge of the gravity of the morbid process and the resistance of the individual, thus being of value in prognosis.—*La Riforma Medica,* March 3, 1906.

Book Reviews.

On the Relations of Diseases of the Skin to Internal Disorders. With Observations on Diet, Hygiene, and General Therapeutics. By L. Duncan Bulkley, A.M., M.D., Physician to the New York Skin and Cancer Hospital; Consulting Physician to the New York Hospital; Consulting Dermatologist to the Randall's Island Hospitals, to the Manhattan Eye and Ear Hospital, and to the Hospital for Ruptured and Crippled, etc. New York: Rebman Company; London: Rebman Limited, 1906.

In this volume Dr. Bulkley has put into permanent form the lectures of his annual course delivered at the New York Skin and Cancer Hospital during March of last year. The great danger to which every specialist is exposed is that of losing his sense of proportion and regarding the diseases with which he deals as something apart and not related to derangement of the rest of the economy. This was at one time particularly true of diseases of the skin, as a consequence of the teachings of the German school, but how wrong these teachings were is very clearly shown in these lectures. The lecturer approaches his subject from the side of the general system rather than from that of the skin; that is to say, he discusses the various disorders of the nervous, digestive, respiratory, and circulatory systems, the organs of sex, of excretion, etc., and reviews the cutaneous disturbances associated with them, rather than taking up the special diseases of the skin and speaking of the constitutional affections associated with them.

There are four lectures, one serving as an introduction to the subject, the two following discussing the general affections mentioned and the various skin manifestations associated with or dependent upon them, the final lecture being devoted to some general deductions from the facts furnished and to the question of treatment. The work is written in the personal and unstilted style of the lecturer, which makes it easy to read. It is a suggestive little book that cannot but be of great assistance not only to the dermatologist, but to the general practitioner as well.

Lectures on Tropical Diseases, Being the Lane Lectures for 1905, Delivered at Cooper Medical College, San Francisco, U. S. A., August, 1905, by Sir Patrick Manson, K.C.M.G., M.D., LL.D., F.R.C.P., Hon.D.Sc., Medical Adviser to the Colonial Office; Lecturer London School of Tropical Medicines, St. George's Hospital Medical School, etc. Chicago: W. T. Keener & Co., 1905.

The author of these delightful lectures needs no introduction, for his work on "Tropical Diseases" ranks first among the treatises on this subject in the English language. The present volume is less comprehensive, as the lecturer chose for his subjects only those affections which his auditors would be likely to meet in their practice among the natives of the countries bordering on the Pacific—a wide enough field, yet not embracing all the territory included in the tropical zone. The book is not a formal treatise, being written, as befits the occasion, in a semi-popular style, but is all the more readable because of this. The several lectures, following an appropriate introduction on the principles governing the geographical distribution of tropical diseases, deal with: Epiphytic Disease, Ankylostomiasis, Dracontiasis, Endemic Hemoptysis, Bilharziasis, Filariasis, Malaria, Trypanosomiasis and Sleeping Sickness, Febrile Tropical Splenomegaly (Kala-Azar), the Diagnosis of Tropical Fevers, Treatment of Fevers and Fluxes, and conclude with a talk on Problems in Tropical Medicine. The work cannot be regarded as a complete and authoritative treatise on tropical medicine, but as an introduction to this fascinating branch of medicine it can be unreservedly recommended. It reads like a story and will be absorbingly interesting to every medical man devoted in his science, whether or not his daily practice brings him in contact with the subjects of tropical disease. In this country and at this time every practising physician, wherever he lives, is liable to be called upon to treat some wanderer suffering from a malady acquired in one of our tropical possessions.

Physiologie und Pathologie des Mineralstoffwechsels. Nebst Tabellen über die Mineralstoffzusammensetzung der menschlichen Nahrungs- und Genussmittel sowie der Mineralbrunnen und Bäder. Von Dr. Albert Albu und Dr. Carl Neuberg. Berlin: Julius Springer, 1906.

The first part of this treatise on the inorganic chemistry of the body is concerned with the details of metabolism and the part in the economy of life played by the various mineral constituents of the human organism. The second part contains an excellent set of tables, giving the composition of the various articles of animal and vegetable food in common use, and of all the more important mineral waters, over one hundred and fifty in number. The book is a very satisfactory exposition of an important subject.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF CALIFORNIA.

Thirty-sixth Annual Session, San Francisco, April 17.

The President, Dr. R. F. Rooney of Auburn, in the Chair.

(Special Report to the Medical Record.)

The meeting of this society was to have occupied three days, April 17, 18, and 19, but the earthquake on the morning of the 18th prevented the completion of the program. It had been the intention of the members to celebrate in fitting manner the fiftieth anniversary of the founding of the society. A program of unusual scientific interest had been prepared, social entertainments of more than ordinary liberality had been arranged for, and clinics at all the leading hospitals of the city had been promised. The meetings of the first day were held as appointed, but the call to duty in the relief of the injured on the succeeding days effaced all thought of further proceedings, had such been possible. Fortunately the members of the society escaped serious injury, with the exception of one, Dr. J. Coplin Stinson of San Francisco, who was killed in the collapse of the California Hotel.]

GENERAL SESSION.

The Address of Welcome, on the part of the San Francisco County Medical Society, was delivered by its president, Dr. Wallace I. Terry.

The Address of the President, Dr. F. F. Rooney, followed. This consisted of an exceedingly interesting review of the history of the society from its organization to the present time, its many trials and struggles during times when the meetings were less formal and challenges more formidable than at the present time. The personal reminiscences of the speaker were highly entertaining.

Board of Medical Examiners.—The President of the board spoke chiefly of the manner in which the law requiring examination had affected the licensing of physicians to practise in the State. This was well shown by the fact that during the year 1901, prior to the law's going into effect, 753 certificates were issued, whereas, during the succeeding five years there have been issued a total of only 691 regular certificates, 40 homeopathic, and 6 eclectic.

Dr. Carpenter spoke of the defects in the present law, and suggested several amendments which would remedy them.

Dr. Dudley Tait discussed the same subject, with particular reference to the irregular practitioners. He referred briefly to the enormous decrease in the number of homeopathists who have been able to obtain licensure through examination as compared to those entering practice prior to the enactment of the present law. But the principal point dwelt upon was the licensing of osteopaths. Something ought to be done, he said, to prevent the unlimited admission of this class, of whom 485 have been admitted to practice in the last five years. Three requirements, he thought, should be made: First, health officers should be compelled to refuse burial permits on the death certificates signed by any unregistered physician or osteopath. Second, all osteopaths should be prosecuted who practise anything above osteopathy. Third, a new member should be added to the board of examiners to represent the osteopaths, and these should then be required to pass the same examination as other applicants, with the exception of practice, thus placing them on the same footing as the homeopathic and eclectic candidates. The speaker stated further that the authority to prosecute unlicensed practitioners should be placed in the hands of the examining board instead of the County Medical Societies, as at present, and the provision which gives half the fine to the informant

should be done away with. With reference to reciprocity between California and other States, he showed that California would be the loser by its adoption, since most of the graduates of institutions in the State remain there. The records show that 181 outside graduates have been admitted to the State on examination to five California graduates licensed in other States. In conclusion, he stated that the Board had revoked three licenses during the past year and contemplated the revoking of two others in the immediate future.

Dr. KING referred briefly to the character of the examinations. He did not regard them as too rigid and defended the statement by statistics which showed that the number of successful applicants in this State is nearly up to the average of those in other States.

Medical Licensure was the title of a paper read by Dr. S. D. VAN METER of Denver, a member of the Colorado State Board of Examiners.

Dr. F. M. POTTENGER of Los Angeles presented the report of the committee on tuberculosis. He considered California in the lead of the States in organization and work accomplished. He laid great stress on the importance of the reporting and registration of all cases of tuberculosis, not for the sake of quarantine so much as for the purpose of thorough disinfection of lodgings after the patient has removed.

SECTION IN GENERAL MEDICINE.

What is Rheumatism? — Dr. WOODS HUTCHINSON of Arrowhead Hot Springs, said that rheumatism was divided into three classes: (1) The acute febrile attacks, with swollen joints, acid sweats, and cardiac complications; (2) rheumatoid arthritis and its varieties; (3) the so-called chronic rheumatism, characterized by persistent recurrences, with little or no rise of temperature, little or no swelling of the joints, and lameness out of proportion to the articular changes. Although the essayist admitted the infectious nature of acute articular rheumatism and the possibility of a similar influence in the production of some of the other forms, he thought that the brunt of attack in all fell upon the peripheral nervous system. Chronic rheumatism, muscular rheumatism, lumbago, and myalgia, he regarded as forms of peripheral neuritis, and he had been struck by the frequency with which such attacks are preceded by some acute infection, more particularly by influenza, tonsillitis, diphtheria, summer dysentery, or whooping-cough. Arthritis deformans, the so-called rheumatic gout, he considered as unquestionably a neurotrophic disorder, probably of infectious origin. Whether it was specific in character or not, has not been determined. Acute articular rheumatism he believed to be a toxic peripheral neuritis, the changes in the joints being secondary. The disease was undoubtedly infectious, but he did not think that the specific nature of the infection had been proved. It might possibly be the result of a number of zymotic diseases. With reference to treatment, he considered the salicylates devoid of specific action or influence on the infectious agent. They were useful chiefly for the relief of suffering, but did not shorten the duration of the disease or prevent cardiac complications. Diet was not of much importance in his estimation. There was at least no prescribable diet. The food should be of such character as to keep the patient in good condition, and this varied with different persons. The diet must therefore be an individual one. The elimination of toxic matter must be taken into account. The rheumatic patient was a neurotic individual and he was therefore peculiarly affected by food. Some could eat meat, lobsters, almost any kind of food, while others must be more abstemious, but not on account of peculiarities belonging to the infection.

Effects of Saline Mineral Waters on Diseases of Metabolism and Nutrition.— Dr. L. D. MEAD of Byron Hot Springs read this paper, in which he reviewed the history of mineral water medication, the attitude of the profession in regard to it in the past and at the present time, the influence of Sir William Roberts, his writings, and experiments, some of which he criticised. The important experimental and clinical investigations of von Noorden and his followers were referred to. This was followed by a review of the essayist's personal experiences in the mineral water treatment of a large number of diseases, particularly in gastric, nervous, and articular affections. Cases were cited to illustrate the relative benefit obtained from the administration of the saline waters and that from change of climate and environment obtained through residence at the springs. Emphasis was laid on the importance of leaving the instruction of patients to the resident physicians. Too many persons come to the resorts with instructions from their home physician to drink quantities of the water which, if it were possible for an ordinary stomach to contain them, would preclude the possibility of indulging in food.

Diet and Hydrotherapy in the Treatment of Rheumatic and Gouty Conditions.— Dr. ROBERT CRESS of Paso Robles Hot Springs read this paper. The speaker attributed greater importance to the benefit of diet in the treatment of these affections than did Dr. Hutchinson and agreed in great measure with the last speaker in regard to the benefits of water both internally and externally applied.

These papers were discussed by Drs. A. J. Sanderson of San Francisco, Dr. Pierce of Colfax, and other members of the society.

The Differential Diagnosis Between True Sciatica and Diseases of the Urethra and Adnexa.—Dr. G. S. PETERKIN of Seattle, Wash., presented this communication. He insisted especially upon the necessity of correct diagnosis. The speaker thought that a great many cases of supposed sciatica were examples of reflex pain arising from pathological conditions in the urethra. This was true of both male and female patients, but it was more often encountered in the male. It is important, he thought, to make a careful examination of the urethra and adnexa in all cases of sciatic pain before coming to the conclusion that the case is one of true sciatica.

SECTION ON GENITOURINARY AND SKIN DISEASES.

This section met in joint session with the Pacific Coast Urological Association. The program embraced three papers and a business session of the section. The titles of the papers were: "A Combination of Syphilis and Epithelioma of the Tongue," by Drs. D. W. Montgomery and H. M. Sherman of San Francisco, "The Etiology and Recent Experimental Work in Syphilis," by Dr. Alfred B. Grosse of San Francisco; and "Alopecia Areata," by Dr. Alexander Garceau of San Francisco.

OPHTHALMOLOGY AND OTOLOGY.

The section of the eye, ear, nose, and throat met in joint session with the Pacific Coast Ophthalmological and Otolaryngological Societies. The following papers were read: "The Amplitude of Accommodation and its Importance in Connection with Eyestrain," by Dr. Edward Jackson of Denver, Colorado. "Subnormal Accommodation of the Eye," by Dr. F. B. Eaton of San Francisco, in which the speaker referred to the frequency of the condition, especially in youth, the obscurity of the symptoms, and the common failure to recognize it. "The Use of the Stenopic Slit in Refraction, by Dr. W. Scott Franklin of San Francisco, who had found most benefit from a slit 1 mm. in width and 5 mm. in

length. Reference was made also to the frequency of careless work in refraction and the too great reliance on individual tests. All tests were only corrohorative. "Ocular Lesions Associated with Constitutional Diatheses," by Dr. H. I. Jones of San Francisco. "General Diseases as a Cause of Diseases of the Eye," by Dr. H. M. Ward of Woodland. "Students' Eyes" by Dr. W. F. Snow of Stanford University. "Report of a Case of Keratitis Fungoides (Aspergilliana)," by Dr. Stillson of Seattle.

Ophthalmological Societies on the Pacific Coast.—A discussion was had on the propriety of continuing the Pacific Coast Ophthalmological Society as an independent organization. Dr. David DeBeck of Seattle, the secretary appointed at the organization of the society at Portland, reported that a large number of specialists along the Pacific slope had signified their willingness to become active members, but some of those present thought that the society should merge with the proposed Pacific coast branch of the Ophthalmological section of the American Medical Association, and a committee was appointed to consider the matter in connection with a similar committee from the Otolaryngological Society.

TENNESSEE STATE MEDICAL ASSOCIATION.

Seventy-third Annual Meeting, Held at Memphis, April 10, 11, and 12, 1906.

The Association met at the Peabody Hotel, under the presidency of Dr. Cooper Holtzclaw of Chattanooga.

Cholecystectomy.—Dr. Battle Malone of Memphis said that practically all surgeons agreed that excision of the gall-bladder was clearly indicated in (1) primary carcinoma of the gall-bladder; (2) gangrene, phlegmon, or empyema of the gall-bladder; (3) when the viscus was badly lacerated, as from gunshot wounds, etc.; (4) in impaction of stone in the cystic duct, which could not be displaced; (5) when the gall-bladder was greatly thickened and contracted. The operation could be done in the average case just as quickly and in many cases more quickly and with as little danger to the patient as cholecystostomy. After drainage of the gall-bladder there were necessarily adhesions which must be a source of more or less discomfort to the patient. In view of the present accepted theory of the etiology of gallstones, it would seem that the adhesions by constant tugging on the gall-bladder would tend to cause a recurrence of cholecystitis and the reformation of stones. As illustrative of this, he reported two cases that came under his observation in which cholecystectomy was performed. While he would not advocate the removal of the gall-bladder as a routine measure, he believed that if the operation was done more frequently there would be less unpleasant post-operative symptoms, and fewer patients would be subjected to a secondary operation. He felt less anxiety for the future of a patient whose gall-bladder had been removed than when it had been drained.

Dr. John L. Allen of Brownsville indorsed the position taken by the essayist with regard to removal of the gall-bladder. If a stone was impacted in the cystic duct, drainage would give more trouble than the removal of the gall-bladder.

Dr. J. A. Crisler of Memphis quoted Murphy as saying that the ideal operation should be drainage of the gall-bladder, leaving the gall-bladder itself in its proper place; that it acted as a drainage tube. He thought the removal of the gall-bladder without drainage was almost a useless operation, unless the operation was done for gangrene, for gunshot wound, or for some traumatic lesion.

Dr. W. A. Bryan of Nashville said he had the pleasure last July of spending some time with the Mayos of Rochester, Minnesota, when he saw them operate on six or eight gall-bladder cases.

Dr. M. C. McGannon of Nashville said that from his reading of the literature he had come to the conclusion that cholecystectomy was being done less and less. He did not think it was essential to remove every gall-bladder that was found to be diseased. A better method of dealing with this subject was to study pathology as we found it.

Dr. J. A. Gaines of Nashville emphasized the fact that empyema of the gall-bladder, unless the organ was markedly contracted, did not ordinarily demand cholecystectomy, but drainage. However, cholecystectomy was often indicated in gangrenous or traumatic conditions.

Dr. Lucius E. Burch of Nashville said that in a case of gangrene of the gall-bladder, or gunshot wound of the gall-bladder, the gall-bladder should be removed. On the other hand, if there were stones in the gall-bladder without any involvement of the cystic duct or of the common duct, drainage should be instituted.

Coprostasis.—Dr. T. J. Happel of Trenton reported the case of a married woman, who gave a history of indigestion, with suffering in defecation, accentuated at each menstrual period. The patient's condition was such that it was necessary to resort to laparotomy. The author emphasized the following points: (1) The necessity of a careful examination per rectum and per vaginam of all cases presenting evidence of long-continued disturbance of the bowel not relieved by medicinal measures. (2) When this was refused, to dismiss the patient, so as to assume no further responsibility. (3) If the patient remained in one's care he should insist on a laparotomy being done promptly, not allowing the patient to get in extremis before an operation was permitted. (4) In this case the gut was found so full that it could not be moved without tearing the gut. (5) The rapid improvement in the condition of the patient after operation. (6) The passage of feces from the rectum after the formation of an artificial anus. (7) The apparent discharge from the bladder of feces on two occasions, and then the cessation of this condition, with the complete stoppage of all leaks into the bladder. (8) Recovery of the patient from what seemed to be, when the abdomen was opened, a hopeless condition.

Dr. John L. Allen of Brownsville reported two similar cases, although their condition was not so marked or distressing. It was difficult, however, to move the bowels of these patients even with enemas. He spoke of the condition as being due to a hypertrophy of Houston's valves, and succeeded in curing these two patients by clipping the rectal valves. Since then he had resorted to this procedure in a great many cases of obstinate constipation, with successful results. He was inclined to the belief that fully 50 per cent. of the cases of constipation were due to a thickening of these valves.

Dr. A. B. Cooke of Nashville congratulated the essayist on the wonderfully good result he had obtained, considering the desperate condition of the patient. He had never seen any such accumulation of fecal matter in the intestinal tract, nor but one patient who was in such an extreme general condition. He thought Dr. Happel was justified in resorting to a laparotomy in this case.

Nephrolithotomy, with Subsequent Nephrectomy.—Dr. W. D. Sumpter of Nashville said the early recognition of renal calculi was important to prevent atrophy, hydronephrosis, infection, pyonephrosis, perinephritic abscess, fistula, and anuria. A timely operation before the patient was in a weakened state was desirable; yet the difficulty was clearly shown in Doran's report that in 24 kidneys and stones found, only 11 had had symptoms of calculi. Aseptic concretions might remain a long time, with no evidence of their presence. The author's patient had no definite pain when the four calculi were in the pelvis of the kidney, until the gravid uterus of six and a half months had pressed upon it, and an abscess resulted. The quiescent state of the kidney, with sixteen stones remaining after nephrolith-

otomy, was corroborated by the citation of similar statistics. Although pain was of great diagnostic value, it was often absent or deceptive. At no time was blood detected in the urine. Frequent urination was absent until two weeks before nephrectomy, but never necessitated emptying the bladder during the night. In nephrectomy for suppurating kidney drainage was of great importance. Whatever the renal lesion, whatever the incision chosen, careful, conservative methods, especially avoiding the causation of shock, which was the greatest factor in the fatal termination of kidney surgery, would be productive of results that were satisfactory in the hands of the painstaking surgeon.

The President's Address.—Dr. Cooper Holtzclaw of Chattanooga selected as the subject for his presidential address, "The Day's Work." He said that the day's work in the life of a busy practitioner of medicine brought forth many things for consideration. It brought many thoughts, good, bad, and indifferent, mostly bad and indifferent. It brought him nearer to actual life than it did most men, and if Pope was correct in saying that "The proper study of mankind is man," certainly the physician's day's work gave greater opportunity to observe both sides of life, the outside as well as the inside. In order that we might be better fitted more correctly and accurately to observe these wonderful phases and phenomena of life and death, it was proper that physicians should be better educated and prepared for this. A college education and a four-year medical course were absolute prerequisites to the practitioner, but to be most successful he must possess the heart of a lion, the brain of an Apollo, the eye of an eagle, and the gentle touch of a lady's hand.

Extrauterine Pregnancy.—Dr. Richard Barr of Nashville reported a case of double uterus, with extrauterine pregnancy. The patient was a negress, aged 17 years. The specimen exhibited showed a distinct double uterus, with two cavities without connection. Each cavity was connected with the corresponding Fallopian tube, and each must have opened separately into the vagina, although careful search of the vagina failed to show the opening of the right organ. The blood cyst of the right tube was taken to be an extrauterine pregnancy, with intratubal hemorrhage, and death of the ovum. The unusual features about the case were the double uterus and extrauterine pregnancy; the fact that the pregnancy had occurred by a route almost impossible of demonstration after removal of the uterus; while on the other side the way was wide open, so to speak. The pregnant tube was twisted around, swinging forward, so that it pointed to the left and rode on the anterior wall of the uterus, while its ovary lay in Douglas's *cul de sac* under the uterus, and was so uninvolved as to be without adhesions to any structures. The shutting off of Douglas' pouch by adhesions left the pocket perfectly normal, which contained the right ovary. The cecum and appendix were mobile; the latter organ was located in a vertical position just behind the median line of the abdomen. The author reported another case of extrauterine pregnancy in a negress, aged 24.

Dr. F. D. Smith of Memphis said that nearly all the cases of so-called hematosalpinx, pelvic hematocele, were probably the result of tubal pregnancy. He reported two cases of extrauterine pregnancy.

Dr. William Litterer of Nashville said that many cases reported as extrauterine pregnancies were not such, but were hematosalpinx or ordinary hematomas.

Traumatic Lesions of the Brain and Skull.—Dr. J. L. Crook of Jackson limited his remarks to fractures of the vault of the skull. The symptoms of these injuries varied materially. All suspected cases were to be operated and inspected. The only occasion where doubt could exist was in fracture of the inner table alone, and here, if there were any localizing symptoms or evidence of intracranial injury, the use of the trephine was justified and demanded. If the case were one of depressed fracture, a medium-sized trephine should be used and the depressed portion elevated, thus restoring the normal convexity of the skull. If the fracture were a comminuted one, the particles should be entirely removed and the edges of the fracture smoothed with the rongeur forceps. The author reported four cases of traumatic lesions of the skull and brain, all of which demonstrated the necessity for prompt exploratory operations in all instances of cranial injury when a positive diagnosis could not be made from the original wound. He said the truest conservatism was that which gave the patient the best chance for a rapid and perfect recovery.

Osteosarcoma of the Lower Jaw.—Dr. Duncan Eve of Nashville removed this tumor of the jaw, which was enormous in size, being ten and a half inches in its vertical diameter and nine inches in its transverse, from a negress. The surface of the tumor was perfectly smooth, and the mass was hard and incompressible over its entire extent. The skin was sound, and there was no enlargement of the superficial veins or infiltration except on the cheek of the affected side. The steps of the operation were detailed. He presented photographs of the patient before and after operation.

What Are the Safest Criteria for the Estimation of Renal Lesions?—Dr. Raymond Wallace of Chattanooga summarized a paper on this subject in this wise: Our methods for accurately estimating kidney pathology were sadly deficient, particularly when based upon the significance of albumin and casts. Extrarenal sources of albuminuria and various so-called physiological or functional forms must be carefully eliminated wherever a shadow of doubt as to actual renal lesion existed. Various clinical data to be found on physical examinations offered valuable aids in diagnosis and prognosis, particularly the detailed history of the case, which might suggest an actual causal factor in past habits, or illnesses; in edema, in retinal changes, in cardiac hypertrophy, and in a pulse of increased tension with an accentuated aortic second sound. Renal capacity, as shown by the urine, was revealed, not so much in the so-called pathological substances eliminated as in a deficiency in the excretion of normal product, as made known by the total twenty-four-hour quantity, the specific gravity, and color.

Local and Regional Anesthesia in Rectal Surgery.—Dr. A. B. Cooke of Nashville pointed out some of the advantages of local anesthesia in rectal surgery. He felt warranted, from personal experience, in claiming that it was simple, safe, and effective. It eliminated the dangers and discomforts of general anesthesia. Pain at the time of operation was usually absent, and always so slight as to be easily borne. Post-operative pain was less by far than after the old methods. The time required for the operation was greatly reduced. Confinement to bed was rendered a matter of expedience rather than necessity. The period of detention from business was diminished fully one-half. Under this method the hospital became a convenience and luxury rather than a dreaded essential. It was a thoroughly reliable means of affording relief in many cases which would otherwise be unsuitable for operation. It robbed these operations of their terrors, and made it possible to reclaim this work from the hands of the "no-knife advertisers."

Doctor, Druggist, and Proprietary Medicines.—Dr. J. L. Andrews of Memphis read a paper on this subject, in which he offered some practical conclusions. The greatest danger in patent medicines was in their indiscriminate use without any sort of judgment. As conditions were now, exactly the same thing was true of proprietary medicine, there being in this respect little or no difference between the two. Druggists, all of them, ought to stop counter prescribing. The author introduced a resolution, which was adopted unanimously, to the effect that the society looked with favor on the establishment of a drug store solely for physicians' prescriptions, and the sale of staple drugs and sickroom accessories—no counter prescribing, no patents, no side lines, cigars, or soda water. The druggist derived only the smallest profit from the sale of patent medicines. The Tsar of Russia was no more

autocratic than the patent medicine sharks. Quite recently an elaborate system had been put in operation by which any druggist, who varied in the slightest particular from a fixed price, could be detected, and in the future he could buy no more of the system's goods. In the face of these restrictions the druggists ought to decline in the future to sell patent medicines. Let the department stores have the patent medicine business. According to a recent statement of a patent medicine maker, women bought and used nearly all the patent medicines that were sold. In the department stores they could buy these things at bargain-day prices to their hearts' content. There could be no question that physicians were now prescribing proprietary medicines to an extent that was reprehensible. The druggist should have a chance to elevate and dignify his entirely worthy profession by efforts at scientific and elegant pharmacy. The physician ought to be able to tell at a glance whether or not his prescription had been properly compounded. For the druggist, the speaker wanted to reiterate that he had none other than the kindliest feeling. He was overworked and underpaid, and Dr. Andrews was in favor of any legitimate measure which would alleviate these conditions. He had a firm conviction that the druggist's best hope of professional elevation and advancement lay with physicians, and it was the plain duty of every physician to exert himself to bring about this end.

Surgical Treatment of Uterine Fibroids.—Dr. J. W. Barksdale of Memphis limited himself to the surgical aspect of these growths, with especial reference to the complications and degenerations with which they were so frequently associated. Operations on fibroids had a mortality of approximately 5 per cent., which was not very much in excess of the average percentage of cases in which the abdominal cavity was invaded for all cases; yet Dr. T. B. Eastman of Indianapolis, in 117 cases operated on, found 43 that presented complications that might have terminated fatally. The author indorsed the position taken by some of the foremost workers in the field of gynecology, who laid down the broad rule that all fibromyomata should be removed as soon as diagnosed.

Appendicostomy.—Dr. G. C. Trawick of Nashville said that this operation was performed first by Dr. Robert F. Weir, about four years ago. The name was suggested by Dr. Willy Meyer. The purpose of the operation was to utilize the appendix as a means of irrigation and the introduction of medicaments through its lumen into the large intestine. That this procedure was justifiable in cases of chronic colitis and sigmoiditis after internal medication and high irrigations had proved ineffectual the author demonstrated. He considered, first, the usual treatment for chronic colitis. The most usual disease for which this operation was performed was amebic colitis; but it had also been done for syphilitic ulcerations of the colon, multiple papillomata, chronic diarrhea with bloody stools, and mucous colitis. The author's experience with this operation had been very favorable. Out of 24 reports of this operation there had been 20 cures, with one death, one result unknown, and one death from pulmonary tuberculosis.

Treatment of Amebic Dysentery.—Dr. John L. Jelks of Memphis had found this disease indigenous in Memphis territory. His investigations had proven to him that the ameba, morphologically at least, was identical with the organism referred to by Musgrave and Strong in Manila, by Shiga and Lafleur and others, and was the chief pathogenic factor of this disease. He thought that in the vast majority of cases the sigmoidoscope could be made to pass all visible foci of invasion, yet in some of these cases the disease had been of long duration. Extensive undermined ulcers seemed to extend down to the muscular coat, and in one case an abscess developed in the liver. As to treatment, the author disinfected the entire colon by flushing through a tube of his own design with a solution of fifteen to thirty minims of formalin and a teaspoonful of boracic acid to each quart of warm water, which fluid passed out through the drainage tube. He then introduced through a small tube with a piston syringe one ounce of olive oil and a dram of bismuth subnitrate. This latter mixture relieved the painful effects of the formalin solution, and furnished a protecting coating to the inflamed viscus. Later, when the patient was placed in the genupectoral position, the proctoscope or sigmoidoscope was introduced, and all ulcers were cauterized with silver nitrate, thirty to sixty grains to the ounce. The entire inflamed area was then sprayed with an antiseptic dried and insufflated with aristol and boracic acid.

Life Insurance Examinations.—A resolution was unanimously adopted by the association, "That the Tennessee State Medical Association recommends to all affiliated county societies to make no insurance examinations for old line life insurance companies for less than $5. This resolution is to have no bearing upon those fraternal orders where the examinee pays for his own examination.

No State Journal Wanted.—In the House of Delegates the matter of whether the association should continue to publish its proceedings in an annual volume or in journal form was brought up by Dr. G. C. Savage. After an animated discussion it was decided to continue the publication of the annual volume of Transactions. The general consensus of opinion was that the time was not ripe for the publication of a monthly medical journal.

The following papers were read: "The Significance of Disturbed Reflexes," by Dr. Michael Campbell, Bearden; "Hemorrhage in and Around Nerve Tissue," by Dr. Hazel Padgett, Nashville; "Injuries of the Eyeball, with Report of Cases," by Dr. J. W. Price, Memphis; "Pterygium: Its Relation to the Refraction of the Eye,' by Dr. George H. Savage, Memphis; "The *Treponema Pallidum* of Syphilis," by Dr. Wm. Litterer, Nashville; "Vesical Fistulæ in Women," by Dr. W. A. Bryan, Nashville; "Rectovaginal Plastic Surgery," by Dr. M. C. McGannon, Nashville; "Notes on Cases of Gastroenterostomy for Chronic Digestive Disorders," by Dr. W. D. Haggard, Nashville.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. L. A. Yarbrough of Covington; *Vice-Presidents,* Drs. J. L. Andrews of Memphis, A. B. Cooke of Nashville, and J. R. Rathmell of Chattanooga; *Secretary,* Dr. George H. Price of Nashville, reelected; *Treasurer,* Dr. W. C. Bilbro of Murphreesboro, reelected; *Delegate to the American Medical Association,* Dr. T. J. Happel of Trenton; *Alternate,* Dr. Heber Jones of Memphis.

Nashville was selected as the place for holding the next annual meeting in 1907.

MEDICAL ASSOCIATION OF GEORGIA.

Fifty-Seventh Annual Meeting, Held at Augusta, April 18, 19, and 20, 1906.

Dr. W. Z. Holliday, of Augusta, President.

The Proper Management of Chronic Suppurative Inflammation of the Middle Ear.—Dr. Dunbar Roy of Atlanta said there were two kinds of chronic discharges: (1) A catarrhal, mucoid secretion, free from odor except when the ear had not been cleansed for some time, coming from the middle ear through a perforation in the drum, associated with the same kind of catarrhal secretion in the nose and nasopharynx. This condition could nearly always be cured by local therapeutic measures directed to both the ear and the nasal mucous membrane. This form of middle ear discharge was frequently seen in children, especially those with adenoids in the nasopharynx, and in those recovering from measles and scarlet fever. Proper and thorough treatment of this form would effect a cure. Frequently the only thing necessary was the removal of the adenoids. However, if the condition was not treated, it would pass into the next form. (2) Discharge from the middle ear of a whitish, desquamated epithelium, with purulent fetid secretion, destruction of the drum membrane, and in many cases erosion and liquefaction of the auditory

canal at the point where the drum should exist. This was the form that must usually be designated as chronic. The treatment of chronic suppurative otitis was divided into two heads: (1) Conservative, or such as were treated by the local application of medicinal remedies; and (2) radical, or such as were treated by surgical intervention. These two forms were dwelt upon at length. In the performance of the radical operation upon the middle ear the author said that the occurrence of the following results should be considered and intelligently placed before the patient or his parents before the same was undertaken: (1) Injury to the facial nerve, with a consequent facial paralysis for a more or less definite time. (2) A loss in the amount of hearing power in that ear, as compared to that which existed before the operation. (3) A possibility that the discharge might not be entirely cured. (4) A last possible result that hardly needed to be considered, and that was an injury to the sigmoid sinus, an accident not likely to happen to the careful operator. The technique of the operation was described.

Dr. C. L. Williams of Columbus reported the case of a boy, 12 years of age, which illustrated very strikingly the fact that discharges from the ears of patients ought not to be viewed lightly.

Dr. R. B. Ridley of Atlanta said the longer he practised and saw cases of chronic ear trouble, the more thoroughly was he impressed with the fact that the radical operation was the only treatment for chronic suppuration of the middle ear.

Dr. L. Amster of Atlanta said that in many cases the physician should be censured for not paying early attention to these cases of ear discharge, which eventually developed into chronic middle-ear trouble, especially after measles, scarlet fever, etc.

Dr. J. L. Hiers of Savannah denounced in the strongest terms the insufflation of powders in these cases, as in his hands they had been more harmful than beneficial. The wet treatment, syringing with strong antiseptic solutions, was best suited to the individual case. He emphasized the importance of using the dry treatment and of packing the ear lightly with absorbent gauze, preferably bichloride or iodoform gauze.

Dr. Henry R. Slack of LaGrange had found that the wet treatment was decidedly the best, especially if it had to be intrusted to a member of the family. In getting rid of granular conditions in the ear he had frequently found nitrate of silver very efficacious.

Some Remarks on Chronic Conditions.—Dr. H. McHatton of Macon said that with the present relative positions so commonly held and the lack of correlation between the various medical attendants, a patient was still in extreme danger. To illustrate, he had a patient some time since with an active secondary syphilis, which in due course invaded two organs presided over by specialists. He promptly consulted the most accessible authority on each organ. Each authority made a diagnosis of syphilis, and put the patient on the mixed treatment. As each of them had every reason to believe that he was the only attendant, and the patient was very good about taking his medicine, the result was most unpleasant. To his brother practitioners he would insist that when a patient came to him who was not directly under the observation of a general practitioner, whose general condition could not be fully and absolutely accounted for by the local lesion which he was treating, it was as much his duty to refer said patient to a competent general practitioner as it was for the general practitioner to refer him to the specialist, and even more so, because a life was often lost that could be saved. The innocent patient had every reason to believe that he was getting the full benefit that could be derived from medical science when he was not. Many errors in diagnosis were not from lack of knowledge, but from incomplete examinations and insufficient time for observation of the case. One should not hesitate to tell a patient that he did not know what the disease was, and it might take time and repeated examinations to make an accurate diagnosis.

This paper was discussed by Drs. Dunbar Roy, W. S. Elkin, J. L. Hiers, St. J. B. Graham, R. Lattimore, Louis H. Jones, L. Amster, J. C. King, C. L. Williams, M. A. Clark, W. B. Hardman, E. B. Bloch, and S. A. Visanska, all of whom took the position that the work of the specialist should go hand in hand with that of the general practitioner.

Needed Legislation on Pure Food Laws for Georgia.—Dr. O. H. Buford of Cartersville, in a paper on this subject, said that it devolved on the medical profession to educate the masses to see the importance of having wholesome food, to build strong bodies, so that they might withstand the inroads of disease. The medical profession of the State wielded great power for good if they would realize that they were the watchmen on the towers. The author made an eloquent plea for more stringent laws with regard to pure food.

Dementia Præcox.—Dr. J. W. Mobley of Milledgeville said that dementia præcox was a chronic progressive psychosis with a peculiar tendency toward dementia, and having its determining features represented in a peculiar chain of symptoms of excitement, delirium, stupor, mannerisms, negativism, verbigerations, stereotypy, and *cerea-flexibilitas*.

Anterior Poliomyelitis.—Dr. J. Cheston King of Atlanta said that an opinion could not be given as regarded recovery from this condition until paralysis took place. At the expiration of two weeks the muscles that reacted to faradism would recover, and those that did not react would either be permanently paralyzed or partially so. In the latter case, as long as the retention of reaction to the constant current remained, there was some hope that the faradic reaction might return, and with it the power of the muscles. At the onset of the attack the patient should be kept quiet in bed and should lie on the face or on one side, and hot applications be made to the spine. He said we could not repair the destruction of cells, but we could facilitate recovery by maintaining the nutrition of the paralyzed parts. When the attack was due to cold the limb should be kept warm from the first; diaphoretics, as liquor ammoniæ acetatis and citrate of potash, should be given. He also recommended the use of ergot and belladonna. After the disease had assumed the stationary condition cod liver oil and tonics were used. Local treatment should not be used until at least a month had elapsed. The limb should then be bathed in hot salt water, and rubbed with a rough towel, and especial care should be taken to keep the limb warm with thick stockings. The muscles should also be systematically rubbed every night and morning. The constant current should be used, both because it dilated the blood-vessels of the part and because the muscles would contract under it and not under faradism.

Paramyoclonus Multiplex.—Dr. E. Bates Bloch of Atlanta reported a case of this affection. The case was interesting not only on account of the rarity of the affection, but the rapidity of the muscular contractions, which far exceeded any other case the author had ever heard of, in that the greatest number of muscular contractions in any case reported heretofore had been 180. While many writers preferred to class this disease with hysteria, it seemed very doubtful if this was the proper view to take of it, in that the motions were such as could not be imitated by any effort of the will, and also that not only individual muscles might be seized with these shock-like contractions, but even portions of the muscles might be so affected, and the violent muscular contractions might take place even without locomotor effects. This disease was very commonly associated with epilepsy.

Recent Studies in Rabies.—Dr. James N. Brawner, Atlanta, referred to the work of Pasteur, Negri, and others. He called attention to the discovery of certain bodies in the central nervous system of animals dead of rabies by Negri, which Negri believed to be the specific

germ of this disease. The value of these Negri bodies as a means of rapid diagnosis was now generally recognized. When the brain of an animal was examined and Negri bodies were found, the evidence was considered positive and a diagnosis of rabies was made. At the Georgia Pasteur Institute, within the last 18 months, the author had demonstrated Negri bodies in 42 dogs and 3 cats, and in every instance the rabbits inoculated died of typical rabies. In three cases in which the inoculation test resulted positively, no bodies were found, although only the hippocampus major was examined and the animals were killed in the first stages of the disease. In 15 dogs and 2 cats, proven not to be rabid, no such structures could be demonstrated. In conclusion, the author said that we now had a reliable method by which the diagnosis of rabies in animals could be made in a few hours.

Specific Organism of Syphilis.—Dr. C. R Andrews of Atlanta described a method of staining *Spirochæta pallida.*

Gallstones.—Dr. George R. White of Savannah read a paper in which he discussed the diagnosis and treatment of gallstones. He reported eight operative cases, and to these he added two others, illustrating the different phases of the disease.

Dr. J. T. Rogers of Savannah followed with a paper in which he discussed at length the differential diagnosis of gallstones.

Typhoid Fever.—Dr. J. E. Sommerfield of Atlanta reported a case of typhoid fever which was followed by abscess of the liver. On aspiration pus was found. Immediate operation was advised, and was performed by Dr. F. W. McRae, who made an incision in the ninth intercostal space and evacuated a large quantity of pus. The patient recovered.

Is There a Continued Fever Other Than Malarial or Typhoid?—Dr. J. W. Palmer of Ailey said that from a clinical standpoint he believed that all questionable cases of continued fever were a variety of mild, uncomplicated cases of typhoid fever, except occasionally they might be malarial. In brief, the author believed that all cases thought to be a third fever, when simmered down to a correct diagnosis would prove to be tvphoid.

The General Practitioner as a Factor in Surgery.—Dr. R. R. Kime of Atlanta said the physician bore a threefold relation to surgery. The first and most important was the prevention of the necessity for surgery. Second, the physician might be a causative factor in developing directly or indirectly conditions that required operative procedures. Third, the physician was often called upon to use his judgment and advise his patient either for or against operative procedures. To secure the best results and place surgery and medicine on a higher scientific basis, the work of the physician and surgeon should be more closely associated and combined with that of the anatomist, physiologist, and pathologist.

Addison's Disease.—Dr. Wm. Clifton Lyle of Augusta reported a case of this disease which came to postmortem. The special points were the freedom of the sclerotics and roots of the nails from pigment; the dark lines of the juncture of the skin and mucous membrane of the lips, and in creases of palms; the hemophilia, acetonuria, the atrophy of the suprarenals, uncommon in persons of that age (55), and the decided improvement consequent upon the administration of suprarenal substance. In this disease, even when marked improvement took place, the patient's life, owing to the abolished function of the suprarenal glands, was extremely precarious, and all patients who had greatly improved or had apparently recovered, should lead inactive lives. They should be warned that they were not cured; that the morbid conditions were still present, and that any overexertion or undue exposure liable to depress the heart, might be attended with grave danger.

Sarcoma.—Dr. O. L. Holmes of Covington reported a case of vaginal sarcoma in an infant, 7 months of age. He presented a study of all similar cases found in the literature.

Intussusception.—Dr. Marion McH. Hull of Atlanta read a paper on this subject, in which he devoted considerable attention to the diagnosis, and said that the principal object of his paper was to aid in making an early diagnosis so that early operation might be performed. He believed that this was the only rational treatment. High irrigation might be used with advantage to aid in reducing the intussusception.

Diagnosis and Treatment of Pulmonary Tuberculosis.—Dr. H. F. Harris of Atlanta said that the treatment of this disease along modern lines was simple. Briefly stated, it consisted in putting the patient practically out of doors night and day, in rest as long as the disease was active, and in supplying a sufficient quantity of good wholesome food. When treated in this way patients improved to an incredible degree in a short time, and where the disease was purely incipient, six months to a year would suffice for a complete cure in a large number of instances. The legislature of Georgia, at its last session, passed an act ordering investigation as to the feasibility of erecting a State sanatorium for the treatment of tuberculous patients.

Early Diagnosis of Pulmonary Tuberculosis.—Dr. T. E. Oertel of Augusta called attention to the distressing frequency with which cases of pulmonary tuberculosis passed unrecognized until they had become almost hopeless, and urged the necessity for more careful methods of diagnosis.

Appendicitis.—Dr. Floyd W. McRae of Atlanta presented some general observations and statistics regarding this disease. He said the cardinal diagnostic points were pain, general or localized; muscular tension on light palpation; tenderness on deep palpation, with or without an appreciable tumor. He laid stress on the point that appendicitis was first, last, and all the time a surgical disease, although not always under all conditions an operative one. Early diagnosis and prompt operation in all cases would reduce the mortality to less than 2 per cent.

Several other papers were read and discussed.

The Pure Food Bill.—A preamble and resolutions were adopted to the effect that the pure food bill at present before the Congress of the United States, known as the Hepburn Bill, met with the approbation of this body, representing the medical profession of Georgia, and that the association earnestly requested the Senators and Representatives in Congress from the State of Georgia to vote for the said bill, and to use all their influence to further its passage.

Life Insurance Examinations.—It was also resolved, that it was the sense of the association that the minimum fee for life insurance examinations should be $5.00.

Officers.—The following officers were elected: *President,* Dr. H. H. Martin of Savannah; *Vice-Presidents,* Drs. T. E. Oertel of Augusta, and J. W. Palmer of Ailey; *Secretary-Treasurer,* Dr. Louis H. Jones of Atlanta; *Delegates to the American Medical Association,* Drs. T. D. Coleman of Augusta, George R. White of Savannah, and H. F. Harris of Atlanta.

Savannah was selected as the place for holding the next annual meeting.

The Sterilization of Surgical Knives.—Grosse has solved the problem of rendering knives sterile without impairing their cutting edge or causing rust spots to appear, by the following procedure: Glass tubes resembling large test tubes in form are provided with racks for the knives and with a suitable stopper. The closed tubes are placed for ten minutes in the steam sterilizer. The knives are in this way rendered absolutely sterile, as enough moisture is present in the air contained in the tube to effect thorough steam sterilization, but on allowing the tube to cool the moisture condenses on the glass and not on the metal, so that there is no danger of rusting.—*Archiv für klinische Chirurgie.*

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 6, 1906.

The President, Dr. T. Mitchell Prudden, in the Chair.

Three Cases of Cervical Rib.—Presented by Dr. Lewis A. Conner. This condition, the speaker thought, must be much commoner than was generally supposed. Although, up to a year or two ago (1904), only 34 cases had been recognized during life, a good many more cases had been met with in the dissecting room. The supernumerary rib usually sprang from the seventh cervical vertebra; more rarely from the sixth. In two-thirds of the cases the condition was bilateral. The ribs varied in length, sometimes barely projecting beyond the transverse process of the vertebra; sometimes extending quite around the anterior of the thorax, and even uniting with the first rib or sternum. In a small percentage of the cases the condition gave rise to very definite symptoms, which were due either to pressure on the brachial plexus or to interference with the circulation through the subclavian artery; the artery was sometimes lifted up and flattened, simulating an aneurysm, or even a true aneurysm might be produced.

The first case shown by Dr. Conner was a man of 55 years, treated in the Hudson Street Hospital for chronic nephritis. The supernumerary rib could be felt on each side directly above the clavicle, but on the left it projected somewhat further forward and had lifted up the subclavian artery so that this could be seen and felt as a broad pulsating mass quite suggestive of an aneurysm. There were no subjective symptoms.

The second case was that of a young girl of 17 years, who for several months had had almost constant pain in the left shoulder. There was also occasionally slight pain in the arm when the elbow was straightened suddenly. It was probable that this pain was due to the presence of the cervical rib, but as there were in the patient a few signs suggestive of incipient phthisis, this question had not yet been definitely settled.

The third case, a woman of 30 years, had been recognized by Dr. Patterson in the course of a routine examination in the dispensary. There were no symptoms.

In all these cases the ribs were bilateral. Radiographs of all the cases were also shown.

Dr. M. Allen Starr said that in a case of brachial neuritis in a woman, 28 years old, who had applied for treatment at the Vanderbilt Clinic recently, Dr. S. P. Goodhart, after examining her, came to the conclusion that her symptoms were due to the presence of a cervical rib. The diagnosis was confirmed by an *x*-ray picture, which showed a supernumerary rib on each side attached to the first rib. The brachial neuritis was undoubtedly due to the pressure which a rather tight collar and thick dress exerted on the nerves that passed over this rib.

Two Cases of Marked Venous Obstruction.—Dr. W. Gilman Thompson presented these patients through the courtesy of Dr. Theodore B. Barringer, Jr. The first case was that of a man, 39 years old, with an aneurysm of the transverse arch of the aorta. About seven weeks previously, without any previous symptoms, and while apparently in good health, he had a fit of coughing, and felt something "snap" near the left collar-bone. This was immediately followed by a swelling in that region, and the gradual development of edema of the left shoulder, arm and hand, together with considerable pain. He came under Dr. Barringer's care, who had an *x*-ray picture taken, which showed an increase in the shadow of the transverse arch of the aorta. There was marked distention of the veins over the anterior aspect of the left shoulder and chest, with a good deal of edema, which still persisted in part. The case was of interest, Dr. Thompson said, on account of its sudden onset and the extreme degree of the swelling and venous engorgement. There was no bruit, nor was there any difference in the pulsation of the two radial arteries.

The second patient shown by Dr. Thompson was a man of 62, with a very marked engorgement of the inferior mammary vein and the posterior azygos vein on the right side, together with a number of the superficial abdominal veins. The case was one of pulmonary tuberculosis, and Dr. Barringer, who had studied it very carefully, had come to the conclusion that the venous obstruction was very likely the result of enlarged bronchial glands pressing upon the superior vena cava, apparently below the entrance of the inferior mammary vein into the innominate. An *x*-ray picture showed some enlargement of the bronchial glands, and infiltration of the right lung.

Dr. Theodore B. Barringer, Jr., said that several cases similar to this one had been reported in which the obstruction proved to be due to a sclerosis of the bronchial glands, which exerted pressure on the superior vena cava.

Dr. Thompson said the chief point of interest in connection with the second case he had shown was in regard to the etiology. The explanation offered by Dr. Barringer, namely, that the venous engorgement was due to pressure produced by the enlarged chain of bronchial glands, was probably the correct one. In connection with such a condition, the question naturally suggested itself whether there was any congenital defect in the vascular walls. In a somewhat similar case, which was operated on by Dr. Briddon at the Presbyterian Hospital, and subsequently reported by him, there was an enormous distention of the veins of the abdominal wall, which was supposed to be due to a congenital defect in some of the superficial veins in connection with a large nevus. Upon operating it was found that the process extended deeper than had been anticipated, and the patient bled so profusely that it was impossible to complete the operation.

Cerebellar Apoplexy.—By Dr. M. Allen Starr. (See page 737.)

Dr. Charles L. Dana, in speaking of the frequency of cerebellar apoplexy, said that one of his students had written a thesis on the general subject of apoplexy last winter, in which he had collected 183 consecutive cases occurring in Bellevue and other hospitals, and of that number four were cases of cerebellar apoplexy and three of cerebellar softening. These figures, Dr. Dana said, corresponded very closely with his own statistics as showing the comparative frequency of the cerebellar cases, which was about 3 per cent. The symptomatology of cerebellar apoplexy had been very accurately described in Dr. Starr's paper, and was well illustrated by his cases. There was another type of the condition which was, perhaps, most frequently met with in hospital practice. Its usual mode of onset was with headache and vomiting, and intense vertigo, followed, in the course of a week or earlier with symptoms of bulbar compression and involvement of the fourth ventricle. These patients were usually brought into the hospital in a comatose state, and died in the course of a few hours with Cheyne-Stokes respiration, disturbances of the pulse, etc.

Dr. Dana said that cerebellar conditions had in recent years excited a considerable degree of special interest, and he felt confident that more light would soon be thrown upon that subject, especially in connection with symptoms that had hitherto been usually attributed to the ear or stomach, or to general neurasthenic conditions. He recalled one case of typical cerebellar hemorrhage which had been treated for five or six years as one of neurasthenia, and he expressed the opinion that many of the asthenic and unusual functional conditions might be explained by cerebellar disturbance. The condition of asthenia or so-called asynergy which was accompanied by great exhaustion lasting for a number of hours, and in which the patients sometimes allowed objects to drop from their hands because of weakness, was rather characteristic of cerebellar disturbance. The suggestion made by Dr. Starr that persistent vertigo in old people pointed to cerebellar, rather than to ear or stomach trouble, was very significant. With cerebellar trouble, the position of the head was often

very characteristic. The head was held up straight, as though the patient was balancing something on it, and there seemed to be a disinclination to turn the head suddenly without at the same time turning the whole body.

Dr. Francis P. Kinnicutt suggested that some of the lighter attacks of vertigo in old people were due to an intermittent claudication of sclerosed cerebellar vessels.

Dr. Starr thought that such an explanation was very probable, and he said that in many instances, instead of being regarded as aural or gastric in origin, the milder attacks of vertigo should be looked upon as one of the prodromata of cerebellar apoplexy, and placed in the same category as were temporary attacks of numbness of the hand or foot, or a transient difficulty of speech.

Dr. Edward G. Janeway said that vertigo was a very troublesome symptom for the physician to deal with, and was often difficult to classify. While physicians, as a rule, were too apt to consider the stomach or ear responsible for such attacks, a certain percentage of the cases were doubtless attributable to those organs. In the more persistent forms of vertigo, however, a cerebellar origin seemed probable, and in dealing with those cases the physician was easily misled by the vomiting, which was a very usual symptom.

Dr. Starr said he would hesitate to make a diagnosis of cerebellar apoplexy in a case where the only symptom was transient attacks of vertigo. It was in the severe, persistent cases that diagnosis should be suspected.

Dr. Attilio Caccini of Rome, Italy, reported two cases of cerebellar apoplexy in which the symptoms were very similar to those described in Dr. Starr's paper, among the more prominent being dizziness, nausea, vomiting, and pronounced nystagmus. In both cases the patients were young men who, after severe attacks of tropical malaria, developed post-malarial anemia; in both there was hematemesis, and in both the autopsy showed a cerebellar hemorrhage.

Radiographs of Fracture of the Humerus Simulating Malignant Bone Disease.—Dr. Robert Abbe reported a case which had been referred to at a previous meeting of the Society. It was that of a boy of 10 who, while throwing a stone into a chestnut tree, sustained a spontaneous fracture of the right humerus. Prior to the accident he had never complained of pain in the arm, nor were there any symptoms of bone disease. An x-ray picture taken subsequent to the fracture showed a remarkable expansion of the shafts of the humerus with thinning of its walls and an appearance of vacuolation in the medullary space resembling internal sarcoma. This, coupled with the manner in which the accident had occurred, led to the belief in pre-existent malignant disease of the bone. In order to verify that diagnosis the bone was trephined and a section removed for microscopic examination; this showed only blood-clot and some reparative tissue. Healing went on without interruption, and now, six months after the accident, the boy was entirely well. The case was interesting, Dr. Abbe said, on account of the false impression created by an unusually accurate radiograph.

Dr. Kinnicutt said that during a recent visit to Boston he saw six or seven cases of spontaneous fracture, and in every one of those instances it was shown subsequently that they were due to metastases resulting from malignant disease of the adrenals.

Lantern Slides Showing Sea Air Treatment of Tuberculosis in Bones and Glands in Children.—Dr. John Winters Brannan gave an interesting lantern slide exhibition of the fresh air treatment of tuberculosis of the bones and glands in children, as carried out at the Sea Breeze Hospital at Coney Island.

Burns.—J. D. Maddox considers that the application of pure carbolic acid is the ideal first treatment for all burns, and states that it is almost magical in relieving the pain. Healing is hastened and the formation of sound new skin is favored.—*American Practitioner and News.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 5, 1906.

	Cases	Deaths
Tuberculosis Pulmonalis	375	193
Diphtheria	339	49
Measles	1348	39
Scarlet Fever	231	21
Smallpox	6	.....
Varicella	103	.....
Typhoid Fever	19	7
Whooping Cough	35	9
Cerebrospinal Meningitis	33	32
Malarial Fever	.....	.....
Totals	2,489	350

The Effect of Intestinal Extract on Blood Pressure.—Roger and Josué have made various experiments with the extract of rabbit's intestine. The intestine was macerated in salt solution, and this extract injected into the bladder of rabbits brought about a lowering of arterial pressure. This effect was produced rapidly, within a minute after the injection. The maximum effect was noted at the end of five minutes, and persisted for a short time. Ten c.c. of the extract, a dose which has often proved fatal, was used in this experiment. Single weak doses had no effect on the pressure.—*Le Progrès Médical,*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service for the week ending May 5, 1906:

THE RUSSIAN RED CROSS.*

By JOHN VAN R. HOFF, A.M., M.D.,

COLONEL, ASSISTANT SURGEON-GENERAL U. S. ARMY, MILITARY OBSERVER WITH THE RUSSIAN FORCES IN THE FAR EAST, 1905.

In summing up its report for 1904 the Central Committee of the Russian Red Cross Society asked, "Has the Red Cross succeeded in accomplishing its difficult task"? and answered, "Undoubtedly; yes!" In proof of this the committee submitted on the one hand the expressions of gratitude from thousands of sick and wounded who during the war had been welcomed to their institutions in the field and tenderly nursed back to health and strength, and on the other hand the testimonials of the army commanders as to the extraordinary services of the Red Cross to the forces in the Far East.

It concluded the report as follows: "Not only has the Red Cross aided the Military Medical Department by supplying necessary *matériel,* not furnished from the Army Medical Magazines, and providing trained nurses, but even organized its own hospitals, flying detachments, dieted rest stations, hospital railroad trains, hospital boats, etc. Moreover, it has taken an active part in the transportation and distribution of the sick and wounded, and has as well looked after their wants both in the field, on the lines of communication and at home, supplying them generously with clothing and everything essential to their comfort. The successful accomplishment of the many and great tasks which have fallen upon us was only possible through the wonderful development of the organization during this war, a development far exceeding anything in its history, and due to the voluntary union of the whole people under the flag of the Red Cross to promote the activities of their National Society."

I will offer for your consideration to-day a brief outline of the plan, scope, and accomplishments of the Russian Red Cross in the Far East, feeling assured that no more important subject than the relation to and utilization of volunteer aid, in the sanitary department of our active armies can be presented for the consideration of this college.

The Red Cross of Russia is one of the grand divisions of the Sanitary Department of that army and, in the language of its statutes, its object is to supplement (*seconder*) the national military administration in the care of the ill and injured in war. In this respect it seems to go somewhat beyond the recommendation of the International Convention of 1863 at Geneva, which was that the Red Cross Society should "cooperate in times of war with the hospital service of the armies by all means in its power."

It will be observed that the Russian Red Cross was actually another medical department, so to speak, which duplicated every unit and function of that department, having its own administration, *personnel,* hospitals both fixed and field, railroad ambulances, boats, sanitary wheeled transport, etc., etc., so that the medical department might have wholly disappeared and its work could have gone on under the Red Cross. To be sure the cost would have been doubled, for as it was Russia paid twice as much for the care of her soldiers in the Red Cross Hospitals as in the military hospitals, but they got more, and getting more did not promote the contentment of the soldier ill in the opposite military hospital who got less. I spoke of this apparent injustice to the officials at the front—I discussed it with the President of the Red Cross in St. Petersburg, and I even mentioned it to the Emperor, and all acknowledged it was not right, though the president was hardest to convince. The Red Cross people claimed that the standards of their institution were higher, that the patients got more and better. I agreed that they got more, but I did not observe that in the essentials the patients in the Red Cross hospitals were any better off than those in the military hospitals, the latter of which were generally better kept though not so lavishly supplied.

The Russian Red Cross is, in the language of the statute, "*sous le patronage direct de Sa Majesté l'Impératrice.*" It has a great social standing, its members are honorary, contributing (*bienfaiteurs*), and active, and embrace a great number of the people, from the royal family down. Its organization now extends widely throughout the country, its income is large and the work done by it during the war is worthy of all commendation.

For purposes of administration the Red Cross is organized into four grand subdivisions. (1) The general (state and county) societies; (2) the Zemstvos; (3) the gentry, and (4) the large individual contributors. The direction of the affairs of the society is vested in the Central Committee, and the respective State and district committees. The Central Committee is located at St. Petersburg, and its president is the executive head of the Red Cross of Russia. This committee has its permanent headquarters at the capital, in a large building known as the Chancellery of the Red Cross, where it met in daily session from the outbreak to the end of hostilities. The Central Committee directs the business of the entire organization, the business of the State and district societies being confined to their own localities. Provision is made for still further subdivision by the organization of branches in towns and neighborhoods which are permitted a measurable control of their own activities. State and district societies are organized by authority of the governor of a province when the active members (of both sexes) number thirty. Town societies must have at least five active members, and are authorized by the governor on recommendation of the State committee. A town may have several such societies. Special committees can be created for fortresses by arrangement between the Central Committee and the Minister of War. The commandant of the fortress is ex-officio president of the Red Cross Committee.

*Lecture II, delivered at the Army War College, session of 1905-6.

The Central Committee consists of twenty-five members elected by the general assembly. This committee submits to the Empress the names of two of its members for the presidency and the names of four for the vice-presidencies of the committee, from which she selects the respective officers, who serve for two years. The president appoints the secretary and treasurer, with the approval of the committee and other subordinate officials. Six members of the committee longest in office are changed annually, their successors being elected by the General Assembly, though the members may be reelected. The State and district societies elect officers, including a treasurer and assistant treasurer, to serve for two years. One-fourth of the members are elected annually.

The General Assembly of the Red Cross is composed of all its members of all classes, and its president is the president of the Central Committee. It meets at St. Petersburg at least annually to examine the accounts of the society, to discuss and determine the questions and measures brought before it, to elect members of the Central Committee, etc., etc.

The regulations governing the Red Cross of Russia are very explicit; they apply as well to peace as to war times, and are well worth the consideration which the limits of this lecture will not permit. It is necessary, however, to consider briefly the specific objects of the society during active operations. They are:

1. To supply women nurses and, if necessary, physicians to the military medical establishments.

2. To supply medicines, surgical instruments and dressings, warm clothing, etc.

3. To furnish hospital stores, delicate food not included in the supply table of the medical department.

4. To assist in the evacuation of the invalids by supplementing the physicians, trained nurses, and orderlies on duty with railroad ambulances, boats, and at collecting and rest stations as well as supplementing the regular supplies.

5. To aid, through the local organizations, the sick sent into the interior of the country, for which purpose it keeps a record of all hospitals and other medical institutions in the region, and if necessary establishes mobile hospitals in which the sick are cared for at the cost of the government, the rate being fixed by the Minister of War.

In case of *necessity* the Red Cross may organize mobile hospitals where the sick will be cared for at a rate fixed by the Minister of War; it may even form *flying hospitals* or *lazerets* for use on the *field of battle*, and *sanitary detachments* to *accompany* the evacuating convoys. It can organize the different means used in evacuating the sick, all of which it actually did in the Far East.

Upon mobilization for active service plans are at once prepared, based on information from the Minister of War, as to probable scope of operations, covering the work of the Red Cross; these having been approved by the Empress, which, of course, means the government, are presented to the General Assembly of the Society. In case of emergency the Central Committee is authorized to take immediate action and report the fact at the first meeting of the assembly.

The work of the Society in the theater of operations is executed by chief delegates, in number corresponding to the number of active armies, and by delegates assigned to each military district. These are elected by the Central Committee, approved by the Empress, and thereafter cannot be recalled except on her authority. Within the empire this work is usually done by committees of the Society or special delegates.

In time of war the functions of the Central Committee are to place at the disposition of and send to its representatives in the field, the *personnel* and *matériel* at its command; to organize the various means necessary to assist in the distribution of the ill and injured within the country, in accordance with the general plan of evacuation indicated by the general staff; to establish supply depots; to execute measures looking to the collection of funds, materials, and medical, nursing, and subordinate sanitary *personnel;* to act on reports, requisitions, and estimates from the field; to audit all accounts, etc., etc.

The chief delegates are the representatives of the Society in the theater of war, and their relation to the military authorities is set forth in pars. 547-571, "Troops in Campaign." A chief delegate is in supreme authority within his jurisdiction and acts under the regulations of the Society and the War Department. His first duty is to assist the military administration by every means at his command, in caring for the sick and wounded, especially by supplying such means as are not in the hands of the military authorities; he distributes all Red Cross *personnel* and *matériel* in accordance with the suggestions of the general commanding.

In the assignment of the women nurses the chief delegate is directed to keep the nurses of each detachment in the same locality, and so far as possible together, so that they will be under the supervision of the chief nurse of the detachment, and he is specially charged to see that the discipline and efficiency of the Red Cross *personnel* is maintained. He establishes supply depots, organizes sanitary railroad trains, convoys, boats, etc. In fact, the principal delegate is authorized to do almost anything, and the more, the further distant he is from the Central Committee. He appoints all of his assistants, though some of the principal appointees must be approved by the Central Committee, and he fixes the amount of their compensation. He is required to report frequently to the Central Committee, and submit detailed accounts of expenditures.

The district delegate represents the Society in his district, and his relation to the military authorities is prescribed in pars. 712, 713 and 725, "Troops in Campaign." He receives his instructions from the Central Committee, and administers the work of the Society within his jurisdiction in the same way as would a chief delegate.

Of course with the coming of war every part of the Red Cross is at once awakened to extreme activity, and happy is the nation that has its Red Cross fully organized and in working order, for to organize it after a war begins means suffering and death to the soldiers, and waste, extravagance, fraud, and noneffectiveness in the organization, for all of which the people are quite likely to blame everyone but themselves. The local committees at once take up the special work assigned them by the Central Committee, chiefly looking to the assisting of the wounded sent to the interior of the country. They appoint representatives on the evacuation commissions of their regions, and to all other military committees organized in the section where the wounded are to be sent. That department of the Red Cross whose special duty in peace time is to organize the sanitary *personnel*, including trained women nurses, sends it to such places as the Central Committee directs and at once proceeds with the recruitment of a new *personnel*.

When it is necessary to organize depots, mobile

hospitals, sanitary trains, convoys, etc., a special delegate is selected by the Central Committee, preferably from among the membership of the local committees.

All organizations of the Red Cross are required to forward periodical reports covering their work, and to render returns of money and *matériel* promised or received, and upon the final completion of the work a detailed and audited account must be rendered.

The regulations lay great stress upon the necessity of keeping a strict account of everything, especially of the fiscal affairs of the various subdivisions. I mention this particularly, as grave charges have been made against the conduct of the society, and specifically against a former president, who was charged with misappropriating the Red Cross funds. As the result of this it was rumored, with what truth I know not, that the early liberal contributions from the people, 11,893,109 R. 77 1-2 Ks., in 1904, ceased and during the latter months the cost of the Red Cross was largely defrayed by the government. I do know that large personal contributions were made by individuals to the very end, but have no data as to exactly how much was contributed in 1905. In this connection I will submit an extract from special report made by the observation committee:

"Statements of alleged irregularities in the management of the Red Cross appear from time to time in the public press, which cannot fail to promote the continuance of the lack of confidence felt by many people in the work of the Society.

"Realizing that publicity and public supervision are the best guarantees that the work of the Red Cross will be kept above all suspicion, and with high respect for the press, the observation committee considers it its duty to call upon the public press to publish the fact, that among the first steps taken by the Central Committee of the Red Cross, was to invite public inspection through the establishment of an observation committee, the membership of which was constituted from the recognized public organizations of the Empire. Representatives were appointed from the gentry and Zemstvos in general, the St. Petersburg and Moscow gentry, the municipal governments of St. Petersburg and Moscow, the St. Petersburg merchants and stock exchanges, and two representatives from her Majesty the Empress's Committee.

"The Observation Committee consisted of fourteen members under the presidency of Count Bobrinski (1905) and through it is realized the public oversight of the work of the Red Cross which so long has been needed. The function of the observation committee is to make itself acquainted with the business of the Red Cross relating to all expenditures for the succor of the sick and wounded in the Far East. At its weekly meetings it considers all questions which arise regarding the work of the Central Committee, to which Committee it communicates its views. Designated members audit the accounts, others consider various special questions, etc.

"The Observation Committee has held forty-five meetings, without cost to the Society. . . . Deeply interested in the success of the work of the Red Cross it realized the necessity for a thorough investigation of all the fiscal affairs of the Society and its agents, and the submission of a detailed report thereon.

"Bookkeeping and statistical divisions are organized in connection with the Central Committee, and vouchers are required with all accounts. Statements compiled by the bookkeeper are audited by the observation committee. Up to the present the following accounts have been verified—Of chief delegate Alexandrovski to September—Chief delegate V. Kaufman to November—Chief Delegate Vasilchikov—etc., etc.

"With view to reducing the expenses of the Red Cross in the cost of *personnel*, the observation committee recommended the substitution of unpaid workers for the paid agents, and thanks to the cooperation of the marshals of the gentry there has been no lack of volunteers, so that of 122 agents 96 served without pay. . . . In conclusion the observation committee takes the liberty to address Russia as follows: 'The Red Cross can be broadly useful to the victims of war only when the public has complete confidence in the way its work is done, for from the public must come the means to accomplish this work. Moreover it needs as well the co-operation of all the public forces, with the establishment of a public oversight of its work. These conditions did not exist up to the breaking out of the war with Japan, and to their absence is undoubtedly due the lack of confidence by the people in the work of the Red Cross, which up to that time collected public offerings, but permitted no public control of its expenditures. If Russia has hitherto really felt lack of confidence in the work of the Red Cross it should be restored now with the organization of the Observation Committee."

Without being able to substantiate the fact, I read between the lines that the expected large resources in *matériel* and money of the Russian Red Cross at the outbreak of hostilities were not realized, the story being that both depots and treasury were empty. The Red Cross, like the Russian Government, neither expected nor was prepared for war. It had a good paper organization and soon enlisted that which is most plentiful in Russia, a considerable *personnel*, the most valuable part of which were the trained nurses. All its *matériel* had to be assembled and sent to the Far East after hostilities began. In a previous lecture I stated that Russia did not provide a sufficient *military* medical department for the armies in Manchuria, as this department had but 8 per cent. of beds east of Lake Baikal. I mention this here simply to show why the Red Cross was forced to supplement the military medical department in every detail, having elsewhere set forth more *in extenso* the inadequacy of the military medical department—*per se*.

For purposes of administration Siberia and Manchuria were divided into two districts which quite closely corresponded to geographical lines. The western or Siberian District embraced the entire line of the Trans-Siberian R. R. from (Samara) Chiliabinsk its western terminus, to Manchuria station its eastern, and included the Amur Valley to Stretensk, covering a distance of about 3,500 miles, of which Senator von Kaufman was principal delegate, with headquarters at Irkoutsk. This district was subdivided by Lake Baikal into the western and eastern sub-districts, the headquarters of the former being also at Irkoutsk, while that of the latter was at Tchita. The country embraced in this district was called the Rear region, though indeed as a practical fact it was the *etape*. The western district had altogether hospital accommodation for 305 officers and 8,901 men, of which about half, viz., 4,226, was east of the lake (the report from the district delegate gives 4,226, while that from the sub-district delegate gives 5,170—I presume the latter is right). The Red Cross *personnel* of the Eastern sub-district numbered: Physicians 100, pharmacists 6, students

(medical) 12, nurses (women) 9, feldshers 23, *under-personnel* 709.

The Red Cross *personnel* of the Western subdistrict included: Physicians 78, nurses (women) 262, *under-personnel* 243.

In addition to the foregoing the *personnel* of certain permanent Red Cross hospitals located in the Western district was employed. This resided permanently in the towns and was paid by the local Society. Altogether there were 1,322 beds in such hospitals at Tomsk, Barnaul, Omsk, Ufa, Samara, etc. The Red Cross authorities were not informed as to the exact number of this *personnel* but estimated one physician to fifty beds and one woman nurse and one orderly to twelve beds. This estimate would give an additional Red Cross *personnel* of physicians 26, nurses (women) 110, sanitaries 110: or a grand total of physicians 204, nurses (women) 381, *under-personnel* 1,103.

I have no doubt this is an underestimate, for I am informed that in the towns the women came in in considerable numbers as volunteers for more or less of the day.

From June, 1904, to September 1, 1905, 172 officers spent 4,010 days in the Red Cross institutions of the district and 16,268 men spent 436,933 days, an average of 23 plus days per officer and 26 plus days per man.

Up to December 31, 1904, only 79 officers and 6,394 men were entertained, an average of 49 plus days each, the officers averaging 80 plus days, and the men 48 plus days.

There were no Red Cross hospital trains in the district east of Irkoutsk, evacuation toward Russia being done by military hospital trains. Thirty odd hospital trains plied between Harbin and Irkoutsk, about half of which were supplied by the Red Cross. I am informed that 120,000 patients passed the Evacuation Commission at Irkoutsk: as but 16,440 remained in the entire district the legitimate inference is that over 100,000 men returned to Russia of whom I was told about 30 per cent. got back to Manchuria.

The District of the Far East embraced so much of Manchuria as remained in possession of the Russians and extended eastward to Vladivostock and the Pacific Ocean—in a word it included the entire theater of active operations. Prince Vasilchikov was principal delegate of this district with headquarters at Harbin. There was a sub-district at the front with headquarters at Gunchalin, another at Vladivostock, and each army had a special delegate representing the Society.

The Red Cross hospital accommodation of this district was approximately 25,000 beds, of which 2,200 beds were actually with the troops in the field exclusive of accommodation in "flying detachments," etc., 1,340 beds were at Vladivostock and the remaining beds at Harbin and towns on the line of the railroad.

The various organizations numbered 150, of which 30 were fixed and mobile dieted rest stations, 18 "flying detachments," and 16 mobile field hospitals.

The estimated *personnel* of the district given to me August 10, 1905 was as follows: Physicians 500, pharmacists 30, medical students 80, nurses (women) 1,500, *under-personnel*, 2,000.

The pay of the senior physicians was 500 rubles monthly. Assistant physicians 350 rubles, pharmacists and medical students 75 to 125 rubles; women nurses and *under-personnel*, 30 rubles, in addition to quarters, subsistence, and transportation. The term of service averaged one year. The Red Cross authorities at Harbin wrote me that from the beginning of hostilities to May 1, 1905, the sick and wounded had spent in the Red Cross hospitals of the district three million days. The actual number treated was not given me. It might properly be inferred that such as were admitted probably remained in the hospitals there for a comparatively short time, as it would naturally be expected that hospitals near the front would soonest be evacuated. This, however, was not the case, if the report be correct. It will be recalled that the official statistics show but 352,412 cases admitted to all hospitals both military and Red Cross. As the latter had but one fourth of the total number of beds it is reasonable to presume that it cared for a quarter of the total number of patients, approximately 90,000 which would give an average of 33 days in hospital for each patient.

The activities of the Red Cross district in the very theater of operations were varied and extensive, and can best be appreciated by a study of the bi-weekly newspaper issued from the Chancery. I learn therefrom that even quite late in the war the system of evacuation was not working smoothly, and that the regulations did not provide for a proper relationship between the principal and district delegates, of the latter of whom it will be recalled one was at the front (Gungalin) and another at Vladivostock. To correct this a paragraph was added to the statutes defining the supervision of the districts and groups, and the relation of the supervisors to their subordinates. Regarding evacuation, very specific orders were issued February 20, 1905, in which the supervisor of evacuation was required to inform himself regarding every railway hospital train leaving the region of the active armies with sick and wounded, and to see that it was equipped with everything necessary both as to *personnel* and *matériel*, for the proper care of the ill. To enable the supervisor of evacuation to carry out his duties special assistants were nominated by him, with the approval of the principal delegate, to every evacuation commission, both in the field and in the line of communication. This is rather an interesting coincidence, as it indicates that previous to that time, about a year after the beginning of hostilities, the Red Cross had no representative on the Evacuation Commissions. I chanced to hear something in this connection which may be of interest. In the early days of the war such system of evacuation of the invalids as existed was defective with the result that men were sent out of the military zone without proper authority. The Red Cross assumed the right to dispose of its patients according to its own judgment and irrespective of the military authorities, and, the story goes, actually did send a large number to Russia. I was told that when the matter was brought to the attention of the military authorities evacuation commissions were for the first time organized, though required by regulations. This story seems to be corroborated by the official order of the Red Cross, of February 20, 1905. Indeed, about this time there seemed to be a general reorganization of the Red Cross in the Far East, and it was then the last battle of the war was fought, on February 22, 1905. An inspector of hospitals was appointed whose duty included the assignment of *personnel*, an intendance official in charge of subsistence, and a medical purveyor. The following month the headquarters chancery was reorganized and divided into six sections:

1. Correspondence; 2, accounts; 3, medical; 4, subsistence; 5, housing, and 6, evacuation.

An orderly administration came rather late in the

day, but it was finally accomplished and was working smoothly just as the war came to an end.

I frequently asked as to the expenditures of the Red Cross, but could then get only general answers, *e. g.* I was officially informed by the Harbin Chancery that the average cost per patient for board and medicine was, officers, 1.25 to 1.50 rubles daily and men .75 to 1.20 rubles. The Red Cross newspaper published the disbursements in the district of the Far East for April, 1905, as follows:

	Rubles.
Administration	12,891.38
Maintenance of hospitals*	214,651.12
Maintenance of floating hospitals	5,086.75
Medical stores, etc.	62,431.06
Maintenance of Red Cross institutions in Southern region	81,089.37
Disinfecting plants	1,321.93
Dental cabinets	884.53
Hospital R.R. trains	65,618.70
Insane hospital	8,000.00
Laundries	435.50
Bakeries	18,358.11
Reserve *personnel*	28,215.61
Miscellaneous (extra)	38,290.91
	537,274.97

Many of the hospitals at the front were being supported by Zemstvos, cities and individuals and there were five railway hospital trains contributed by individuals, so that I am inclined to credit the statement that the total Red Cross disbursements average about a million rubles (half a million dollars) monthly.

While in Russia I had few opportunities to observe to what extent the whole people were really interested in the work of the Red Cross. In St. Petersburg I saw two palaces, which I was informed belonged to members of the reigning family, given over to Red Cross work, and the stately rooms of the Imperial Palace at Moscow were piled high with materials for clothing and surgical dressings, which were being fashioned by the deft hands of the good women of Russia, to warm and succor their country's soldier, even though the war was where and for what they knew not.

What lesson can we learn from the Russian Red Cross? I think several. Our first thought would naturally be of its organization and our first query is, Is such satisfactory? I think not, and the Russians seem to have this view, as I am informed that there will be a general meeting next year during which the experiences of the war will be discussed and a reorganization proposed. Wherein is the organization faulty? Chiefly in the fact that during peace times the society has few activities to vivify it. There are, to be sure, some local Red Cross hospitals which serve as centers of activity, and which do good work as far as they go, but which have only a circumscribed influence. A Red Cross society which will be instantly ready to take up its work at the very beginning of hostilities, *and then is the time when it can be most useful*, must be in continuous activity. To overcome the inertia of inactivity consumes valuable time, is wasteful of effort and costly in every respect. To maintain the activities of such an organization in peace time, and coincidently to keep clearly before the people the true function of the Red Cross, the *succor of the wounded in war,* is a difficult proposition. Even the name must not be too much used or it surely will be abused and the badge must be sacredly preserved for its only lawful use. To meet these essentials most countries have societies subsidiary to the Red Cross, but with distinctive names, and specific functions. In Great Britain is the Order of St. John of Jerusalem, with its ambulance society, with hundreds of members among the working classes, who are trained in the schools of the order, to render first aid to the wounded of the great industrial army in the battle for existence. When the lesser wars come these workers are ready to take, and have taken their places, in the ranks of the Sanitary Department. Over two thousand trained orderlies from the St. John's Ambulance Society were employed in South Africa. In France are like societies, contributing to the Red Cross, but with distinctive names, as is also the case in Austria. But the highest development of the organization of the whole people for humanitarian work in peace that they may be ready for such work in war is found in Germany where the Samaritan Societies reach into every family.

Did time permit, it could well be devoted to a word regarding this wonderful organization of an entire nation, for the purpose of assisting in the care of the victims of war, for it is a shining example to us, who must to the largest extent depend upon our people for such assistance; but I must continue with my immediate subject.

As I understand it the Red Cross is not intended to substitute but to supplement the regular medical department of an army. Of course all students of the military art are aware that no army can maintain in peace a sanitary organization equal to the demands of war, nor can it provide such an organization even in war. The entire nation must help in this work, and whether it is to be well or ill done will depend upon how well the nation is organized and instructed for it.

I have stated that the Russian Red Cross in Manchuria organized all sorts of medical units. This it was apparently forced to do, as the military medical department was inadequate in them all. I find that the Red Cross had in the very ranks of the troops, in positions in front of the enemy, with the first army, nine Red Cross mobile field hospitals and seven Red Cross flying detachments, the second army five Red Cross mobile hospitals and seven Red Cross flying detachments, while the third army had two Red Cross field mobile hospitals and four Red Cross flying detachments. I believe that the sphere of the Red Cross is in the rear of the army and it should not be found at the front except in emergency, and then only after a battle. If required at the front it should come with *personnel* and *matériel*, but not with units; there should be but one kind of hospital with an army, and that should be an integral part of the military organization. I have heretofore alluded to the results of having two kinds of hospitals for the same purpose, the one giving twice as much and costing twice as much as the other, as was actually the case in Manchuria; one in which disicipline was maintained in accordance with regulations, and the other in which the patients were permitted to do much as they pleased, one which was subject to strict military supervision, and the other a semi-independent organization, giving or withholding as its own judgment dictated, and I am reminded of what General Sherman said of an analogous humanitarian effort in our great war, when he found the volunteers from one State being fed on mince pie, while their comrades in a neighboring

*The particulars were given, but will not be here noted except those under II, as follows: Pay of *personnel*, 97,000 rubles; food, 68,700 rubles; buildings and furniture, 22,200 rubles; heating, 8,000 rubles; laundry, 8,400 rubles; animals, 4,700 rubles. The disbursements for evacuation to June 1, 1905, amounted to 315,313 rubles, 46 kopecks.

camp, but from another State, were eating the straight ration and not too much of that.

Surely all soldiers must be treated alike if approximate contentment is to be expected.

The relatively high salaries paid by the Red Cross to its physicians and the greater social and material consideration shown them, occasioned discontent among the army physicians from the Reserve, many of whom, at home, occupied quite as good positions, both professionally and socially, as their colleagues of the Red Cross; moreover the absolute independence of this society of the military medical department caused the higher medical officers to ignore it, and between them there was an armed neutrality, so to speak, which in a less disciplined community would doubtless have broken out into open hostility.

Another important lesson the Red Cross of Russia has taught us is that if we expect the best results in widespread undertakings in which the people are deeply interested, we must take the people into our confidence and let them know exactly what we are doing and what we expect them to do. In the beginning the Russian Red Cross failed in this, and the people lost confidence, so easy to lose and so hard to regain.

If in endeavoring to deduce lessons for our own guidance, from my observation of the work of the Russian Red Cross in the Far East, I have appeared to be unkindly critical of certain features of that society I wish to disclaim any such intention. The work accomplished was beautiful; no matter what the means or cost, without the Red Cross, unless the military department had been largely augmented, which it should have been, the sanitary outcome would have been a failure, whereas now the record is unequaled.

TREATMENT OF CHRONIC DISEASES OF THE HEART BY THE NAUHEIM METHODS: ITS INDICATIONS AND CONTRAINDICATIONS.*

By FRANCIS P. KINNICUTT, M.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY; PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, ETC.

So much has been written in the past twenty years on the Nauheim treatment of chronic cardiovascular diseases that I would hardly venture to choose this theme for a paper were it not that I have been able to study the subject under especially advantageous conditions during the past two years. I took a five weeks' course of treatment in Nauheim in the summer of 1904, and again in 1905. During these visits, besides my personal experience of the treatment, I was granted courteous and full opportunity by Professors Theodore Schott, Heinemann, and Groedel, to see their most interesting cases and to examine the patients to whatever degree and with whatever frequency I desired.

As the result I have been able to form a reasonable opinion of the effects to be expected in cases suitable for what is known as the Schott method of treatment, which is the combination of resistance exercises and baths, and of the contraindications for its application.

Before considering the effects of the baths and the resistance exercises from a clinical standpoint, and their physiological action, I shall refer briefly to the composition of the Nauheim waters and to the technique of both the baths and the exercises.

*Read at a meeting of the New York Academy of Medicine, January 4, 1906.

It may be of interest here to recall that the efficacy of the Nauheim baths in the treatment of many forms of rheumatism had been generally recognized in the early part of the last century. It was the unexpected improvement which was seen to occur in the often associated organic disease of the heart, that led Beneke in 1860 to call attention to the therapeutic value of the Nauheim baths in cardiac disease.

The springs which are used for bathing purposes are three in number. Their chief constituents are: (1) Chloride of sodium, (2) chloride of calcium, (3) carbonic-acid gas, free and in combination.

They vary somewhat in their saline and carbon dioxide content. The range in the chloride of sodium strength is between 2 1-5 and 3 per cent.; in the chloride of calcium, between 1-6 and 1-4 per cent. The free carbonic-acid gas content varies between 1.0074 and 2.3764 parts per 1,000 grams, equaling respectively 574 c.c. and 1,216.6 c.c. In other terms, each liter of the spring richest in carbonic-acid gas contains 1,216.6 c.c. of the gas. The range of the natural temperatures of the different springs is between 31.2° Celsius (88.16° F.) and 35.3° Celsius (95.54° F.).

A system has been elaborated which permits of a wide variation in the saline and carbon dioxide strength of the baths, and as they vary in their different constituents they are known as:

1. The ordinary brine bath (gewöhnliches Soolbad), free from carbonic acid but rich in salines.

2. The thermal brine bath (Thermalbad), rich in salines and containing a considerable amount of carbonic acid in combination.

3. The thermal effervescent bath (Thermal-Sprudel), holding an intermediate position between the thermal and the bath next to be described.

4. The effervescent bath (Sprudelbad), which receives its waters direct from the subterranean springs, with the full saline and carbonic acid content, and with only a very slight diminution in their natural temperature.

5. The current thermal brine bath and current effervescent bath (Strombad and Sprudelstrombad). These baths also receive the water as it leaves the springs. The water forcibly enters at the lowest level of the bathtub, and by means of overflow pipes at the top leaves it throughout the entire period of immersion. The saline strength of the various baths can be increased at will by the addition of the crystallizable waste product, motherlye (Mutterlauge), of the neighboring saltworks.

The course of baths usually begins with the brine or the thermal brine bath, strengthened after a few immersions by the addition of gradually increasing quantities of motherlye. After several days the Thermal-Sprudel, and again after a similar period—usually a fortnight from the beginning of treatment—the effervescing sprudel baths are substituted. The effervescent current baths are reserved for the final days of treatment, and often are not given. The duration of the baths at the beginning of treatment is not longer than six to ten minutes, gradually lengthened to twenty minutes; the latter time is rarely exceeded. The temperature of the first baths is generally from 92° to 95° F. It is reduced with succeeding baths. Temperatures lower than 83° F. are rarely used. Usually not more than two or three successive baths are permitted in as many days, when a day of interval is prescribed. The patient, on emerging from the bath, is wrapped in heated towels and quickly dried by the attendant. Rest for at least an hour, in the recumbent position, is imposed after the bath. The number of baths varies from twenty to thirty-five. The system described gener-

ally prevails, but many variations are and should be made, in my judgment, to adapt both the baths and the exercises, directly to be described, to the individual case.

In healthy subjects the immediate effects of immersion in the baths is a notable diminution in the frequency of the pulse and a slight increase in its volume. Usually there is also a slight increase in the depth of the respirations, with a corresponding decrease in their number. A vasodilatation of the superficial vessels, as indicated by the uniform reddening of the surface of the body, is noticeable. This is especially marked in the effervescing Sprudel bath. The blood pressure has a short initial rise, followed by a depression to or below the original level, succeeded by a renewed rise to its former height.

A series of very careful observations in regard to the effect of the bath upon the pulse were made by me in my own person during my visit in 1904 and confirmed in the summer of 1905. The pulse was taken before undressing, and any increase in frequency during the act was allowed to subside before immersion. After one and one-half to two minutes of immersion, either in the simple brine or in the effervescing brine baths, the frequency was invariably reduced from eight to ten beats, if the pulse was 76 or more before immersion, and its volume was notably increased; if under 70 before immersion, the reduction did not exceed six beats. The pulse rate is usually accepted as a guide for the length of the bath. Its duration invariably should be within the limits of causing any increase in the frequency of the pulse. In my own case, at the beginning of treatment, the pulse rate began to quicken after ten minutes; later in the treatment, an increase in frequency occurred only at the end of a twenty-minute immersion. The reduction in the pulse rate was fully maintained during the subsequent period of rest.

The evidence of vasodilatation of the surface vessels was always well marked, and with it there was a sensation of general and very agreeable warmth following the first sensation of coolness.

The exercises, known as the Schott resistance exercises, used in connection with the baths—a combination to which I have applied the name of the Schott Treatment—were introduced by the late Dr. August Schott and his brother, Dr. Theodore Schott, as the result of elaborate and prolonged experiment. In their words, as quoted by Bezly Thorne,[1] "they consists of movements designed to bring into successive and regulated action almost every collective system of voluntary muscles in the human frame. They consist of slowly-conducted flexion, extension, adduction, abduction, and rotation, in orderly succession, of the arms, trunk, and lower extremities. Each succeeding movement is resisted by an attendant to such an extent as to oppose without arresting it. Each movement must be slowly and evenly made, with a definite and uniform effort on the part of the patient. The office of the attendant is not limited to resisting the movements with equally uniform but slightly inferior force, but it is his duty to impose a short interval of rest after each movement, to enjoin slow and regular breathing, and more especially, by observing the rate of the breathing and its force as indicated by the alæ nasi, to insure that no undue strain is placed on heart or lungs."

The attendant must bear upon but never grasp or constrict the patient's limbs, lest the movement of groups of muscles be impeded or arbitrarily promoted. The resistance, always slight at first, is gradually increased with progressive treatment. The respirations and pulse should largely be the guide for the degree of resistance, and the number of movements given. If either increases in frequency, the exercises should be modified or discontinued. The duration of the single treatment is as a rule fifteen to thirty minutes, including the intervals of rest. There are nineteen different exercises, of the simplest character, and they are fully described, with illustrations, in Bezly Thorne's book.[1] The description of a single one will illustrate the technique. The patient extends his hands in front of him at the level of the shoulder, the palms touching. The attendant, standing in front of him, places his hands on the outer surface of the patient's wrists, which rest in the hollow between his thumb and forefinger. The patient then slowly and steadily carries his arms outward until in a line with the shoulders, the attendant gently and slowly resisting. The arms and hands are then brought to their original position with a similar resistance upon the part of the attendant, whose hands have been slipped to the palmar surface of the patient's wrists. Schott usually advises the daily administration of the exercises, but both the frequency and the number given on a single occasion are properly subject to many variations.

The first exact observations on the effect of exercise, of the contraction of a muscle or a group of muscles, upon the circulation in healthy subjects, were made by Ludwig and his pupils Sczelkow, Sadler, and Gaskell. Further investigations were undertaken by Mosso, Chauveau, Kaufman, Morey, Oertel, von Basch, Comte, Bloch, Moritz, Masing, and others. Lauder Brunton and Tunnicliffe[2] were led by the somewhat conflicting results obtained by the earlier observers to undertake another series of investigations on the effect of resistance exercise upon the local and general circulation in man. Their experiments were conducted with every precaution against error, and the results suggest that an explanation of the conflicting statements made by previous investigators is to be found in the difference in strength of the exercises employed.

In gentle resistance exercises Lauder Brunton and Tunnicliffe constantly observed:

Coincident with the beginning of the exercises a diminution in the pulse frequency (three to four beats) and a rise in blood pressure (ten mm.). During the second half of the movements the blood pressure fell to its original level, the pulse frequency was unaltered. With the cessation of the exercises (thirty minutes' duration) the blood pressure further fell (ten mm.) during thirty minutes, and the pulse rate seven beats in five minutes, at which point both were maintained. After forty-five minutes the blood pressure had risen to its normal level, but the reduction in the pulse frequency persisted. The number of respirations remained the same throughout the exercises. The sphygmogram showed a marked increase in the volume of the pulse during the exercises, the pulsations being nearly double their former size.

Edgecombe's and Bain's experiments[3] on the effect of resistance exercises upon the circulation are confirmatory of Lauder Brunton's. Both series of investigations showed that if the exercises were of sufficient strength to *increase* the frequency of the pulse, the blood pressure was increased throughout their employment.

The physiological effects of gentle resistance exercises in the healthy subject are therefore similar to those produced by the baths, viz., a diminution in the frequency and an increase in the energy of the cardiac systole, an increase in the volume of the pulse, and a diminution in peripheral resistance. The effect upon blood pressure apparently depends upon the relative degree of the increased cardiac energy and

output, and the peripheral vessel dilatation. If the energy and output, or both, are in excess of the dilatation, a rise in pressure results. If the inverse order obtains, the blood pressure after a short initial rise falls to its original level.

If the physiological effects of the baths and exercises are such as have been described, their employment in many forms of cardiac inadequacy—a term expressive of a disproportion between the demand upon the heart and its ability to meet it by whatever cause produced—rests upon a scientific basis and should constitute a potent therapeusis.

Clinical experience indicates that such expectations are in a greater or less degree fulfilled. The degree of success in their employment will depend, as Bezly Thorne expresses it, upon (1) the responsive capacity in the individual case of the nervous mechanism to peripheral stimulation (cutaneous and muscular, an effect of the baths and exercises respectively); (2) the responsive capacity of the vascular tunics; (3) the degree of integrity of the myocardium; and finally I may add, upon (4) a sound clinical judgment and experience in determining these conditions.

The effects of the baths and Schott exercises may now be considered from the clinical standpoint.

In cases of cardiac dilatation suitable for this treatment, one of the immediate effects of both the baths and exercises, in many instances, is a shrinkage in the outline of the cardiac area and the movement inward and sometimes slightly upward of the apex impulse. In the case of the exercises, this observation was originally made by August and Theodore Schott, and their interpretation of it, that it represented an actual diminution in the size of the heart, was at first doubted. Radiographic studies have apparently confirmed their view, and it is generally accepted at the present time by clinicians. The extent of the shrinkage, as estimated by percussion, varies. I have repeatedly observed in my clinical work a shrinkage of a half inch in the left cardiac and an equal one in the right outline after single resistance exercises of twenty minutes' duration, including the intervals of rest.

The diminution in size thus obtained after a single exercise is of very temporary duration, but it is claimed by Schott that with the continued employment of the method a more permanent diminution is effected. My own experience is in accord with this view. In cases of dilated heart without organic valvular disease, to which I shall refer later, the normal size not only is attained, but may remain permanent.

The immediate effect upon the heart is presumably the result of strong reflex influences excited by peripheral muscular stimulation and acting simultaneously upon the cardiac regulator nerves and the vasomotor centers. The response is a more energetic systole (an increased driving power on the part of the heart), and dilatation of the peripheral arterioles, respectively. The dilated heart chambers are more completely emptied, and there is an increased transfer of blood from the venous to the arterial system. If these temporary effects can be sustained, as I believe they are by successive applications of the exercises over a considerable period of time, the purpose of all therapeusis in dilated hearts with loss of compensation is effected.

In the relief of venous hyperemia, the effect of diminished venous stasis in the veins of the heart walls is sometimes lost sight of. It is the first and most potent factor in the establishment of an improved myocardial nutrition. The view which I have expressed in regard to the mode of action of the exercises I would apply also to the baths. The peripheral stimulation differs in kind, but the response is similar.

In attempting to formulate the varieties of cardiac inadequacy suitable for the employment of the methods described, I shall be guided by the experience of those most familiar with this treatment and by my personal observations.

The most numerous and brilliant successes in my experience are obtained in cases of enfeebled, relaxed, dilated hearts, with or without a murmur of muscular or relative mitral incompetence, following prolonged and exhausting diseases, the various acute infectious diseases, and also associated with anemia of varied causation. In some of these cases it is difficult to speak positively of the changes which have occurred in the heart. Possibly there is no more than a loss of tone and relaxation of muscle. In others, especially those following the acute infectious diseases, there undoubtedly exists a parenchymatous myocarditis, granular or fatty, of varied severity. In the anemias, primary (chlorosis) and secondary, judging from the extreme fatty changes found in the heart muscle in the grave forms, a less severe grade of fatty degeneration is probably present. In all these cases there are symptoms of cardiac inadequacy. Such cases are often rebellious to the ordinary methods of treatment. Rest in the strict sense of the term is distinctly harmful. Digitalis, general tonics, and a favorable climatic environment are far less efficient and rapid in their action than the combined use of the baths and resistance exercises.

Under the above head may also be included the cardiac inadequacy which not infrequently follows severe muscular effort, the "heart strain" of many authors. In many instances a very considerable dilatation is present. Rest in these cases is certainly indicated in the beginning of treatment, but a little later the improvement is more rapid under a judicious use of the baths and exercises. The forms of cardiac affections described all come under the head of curable diseases of the heart. Unfortunately the laity is unable and the medical adviser occasionally fails to differentiate the incurable from the curable forms, and patients flock to Nauheim, with or without the advice of a physician, in the hope and often full expectation of a permanent cure of incurable organic disease of the heart.

In incurable organic disease the best results should be obtained in mitral insufficiency with dilatation, and such is unquestionably the case. Where the compensation is maintained with difficulty, and in the early stage of failure, very striking results are secured. Compensation is restored, which is often maintained indefinitely with intelligent care on the part of the patient.

Schott expects much more than this, and I must admit that I have seen extraordinary improvement where a very serious loss of compensation existed. The relief of dyspnea, of passive congestion of the various organs, the amelioration of irregular action, and coincidently a diminution in the size of the heart, has been more rapid than I have seen by any other method of treatment. Groedel believes that less satisfactory results obtain where mitral stenosis is associated with insufficiency. Broadbent, on the contrary, expects good results in such cases.

In aortic insufficiency the consensus of opinion is that little good may be expected from the treatment. Where dilatation is marked, with a corresponding loss of compensation, the treatment may be potent for evil. Broadbent thinks that with the *inception*

of mitral incompetence in these cases some benefit may be expected.

Of the indications for the Nauheim treatment in angina pectoris, one must speak with caution. Defining angina pectoris as a syndrome or symptom group, the clinical pathology of which may differ in different cases, and which has to be determined in each individual instance, which may or may not be associated with gross anatomical lesion, it must be admitted that cases presenting all the symptoms of angina major are sometimes benefited by the Nauheim treatment. Several noteworthy instances have come under my observation. Many of these cases certainly belong either to the functional (hysterical) or vasomotor type, or at least are not due to organic coronary disease. The cases which I personally studied were associated with organic disease of the heart, but certain clinical signs suggested the absence of organic coronary disease. In one of the cases a mitral lesion, which is extremely rare in angina associated with coronary lesion, was present, and the aortic valves were sound; the blood pressure was about normal (150 mm. Riva Rocci) for the age of the patient (sixty-two years). My observations lead me to believe that benefit may be derived from the Nauheim treatment in cases of angina pectoris, presumably of the functional or vasomotor type, and which have not yielded to other therapeutic measures. The absence of aortic insufficiency or stenosis, of a constant arterial hypertension, and of the evidence of a probable *general* arteriosclerosis, should be useful guides in advising this treatment. In its employment much care is indicated; the baths should be warm, weak, and short, and only slowly strengthened.

Is the presence of a general arterioselerosis a contraindication for the employment of the Nauheim treatment? A mere palpability of the accessible vessels, if unattended with arterial hypertension, disproportionate to the age of the patient, certainly should not be regarded.

Groedel regards cases with a blood pressure of 150 mm. (systolic pressure, Riva Rocci) as appropriate for treatment. Pressures above 170 mm. he believes to be unsuitable.

A decision on the advisability of the baths and exercises in myocarditis, other than the forms previously described, is a difficult one. The signs and symptoms of even grave forms are notoriously doubtful. A marked cardiac inadequacy, however, in the absence of evidence of valvular disease and noteworthy dilatation, especially if associated with arteriosclerosis, may reasonably be regarded as a sign of a grave impairment of myocardial integrity, and constitutes, in my opinion, a *positive* contraindication for treatment.

In cases of general emphysema, with its permanent increased pulmonic pressure, a positive contraindication also exists. It is unnecessary to more than mention the contraindication in suspected aneurysm.

Aside from general contraindications for the employment of the baths and exercises, there are equally positive indications for the modification of both in individual cases suitable for treatment. In the case of the baths such an indication is the failure of the usual reaction during and after immersion. In these cases the evidence of at least cutaneous vasodilatation is lacking; the patient experiences a sensation of cold throughout the bath and subsequently, and there is often yawning and occasionally slight nervous rigors. Such a failure of reaction does not necessarily indicate that the treatment is inapplicable; it is often remedied by increasing the saline content of the bath.

In the employment of the exercises, indications for their modification consist in any increase in the frequency of the pulse, of the respirations, of the slightest dyspnea, and of fatigue on the part of the patient. These symptoms may indicate merely that there is a slight disproportion between "demand" (degree of exercise) and "supply" (cardiac energy) and one easily to be corrected.

Indications of the *unsuitability* of both baths and exercises are a marked fall in blood pressure and an increase in the area of cardiac dulness during their administration. The latter sign has recently been observed by me in my wards in the Presbyterian Hospital in a single instance, during the use of exercises of the gentlest form. The case was one of organic mitral incompetence, with dilatation and an almost complete loss of compensation.

I have occasionally observed in my use of the exercises a very slight increase in the area of cardiac dulness, without appreciable change in the blood pressure. It has been in cases of suspected myocarditis without valvular disease. If a modification of the exercises has corrected this sign, I have not regarded the treatment as inapplicable.

I would add a final word on the administration of the exercises. To be efficient they must be attended with "little exertion and no fatigue." A certain amount of training of the patient and a careful selection and instruction of the operator is necessary. To secure the proper conditions, the patient must be taught not to hold his breath or his body rigid (a common tendency), which involves increased conscious effort, to make the movements slowly and very steadily, and to recognize the degree of resistance advised by the physician. The operator should be light of hand, intelligent, and trained in the observation of ordinary symptoms. The use of too great resistance, sometimes at the demand of the patient, is the most common fault of the operator and the most difficult to correct, I have found. At the beginning of treatment I am in the habit of demonstrating the degree of resistance I wish employed in the individual case. In so adapting the treatment, it is needless to say that the pulse rate, the blood pressure, the site of the apex impulse, and the outline of the heart must be noted before and after the first employment of the exercises, and from time to time throughout their use.

I have had convincing proofs in my personal practice of the great benefit to be derived from the use of the resistance exercises *alone* in many forms of cardiac inadequacy. That discrimination and judicious care are required in their application, I have endeavored to show. Schott advises their employment with "self-imposed resistance" as an after-treatment in many cases. It is within the competence of anyone who has become thoroughly familiar with the different movements, and involves little risk of injury through overexertion.

It is to the credit of Schott that he has always maintained that the efficiency of artificial Nauheim baths is similar to that of the natural ones, and there is abundant clinical evidence to this effect. There is equal evidence that results are attainable where the treatment is conducted under the conditions which obtain at well-ordered spas and in institutions which are not seen in cases treated at home.

I was impressed with the mental atmosphere at Nauheim. It was one of hope and cheerful expectation, the stimulus of which must ever be regarded in our therapeusis.

Purposely I have omitted the recital of cases in the present paper. I have chosen rather to give my gen-

eral conclusions, based upon a personal and careful study of these cases.

THE TREATMENT OF TABES DORSALIS.

By F. VON RAITZ, M.D.,
NEW YORK.

Since the recognition of tabes as a pathological entity, various means to overcome this disease have been advocated, tried and forgotten, and to-day, after about sixty years, we are, as far as therapeutic results are concerned, where our predecessors were sixty years ago. To ventilate this subject is, therefore, not an easy and less so a pleasant task, but a frank recognition of defeat generally leads to better efforts and finally to victory. For this reason a free consideration of the treatment of tabes may prove beneficial.

When we treat a disease in a number of patients and find the means employed ineffective, it becomes our duty to abandon them and to study the disease in its etiology, pathology, and symptoms; not, however, so much by perusal of the existing literature, as by inquiring application to the disease itself. Earnest, inquiring application to a limited number of cases will, in time, prove more valuable than routine work on a vast number, because the inquiry leads to independent observation and conclusion, which, sooner or later, exposes the error. There are already many physicians who ignore the present status built for tabes, but they lack courage to express their convictions, often only because they have no confidence in their ability to present the subject properly, or because they fear criticism.

On October 21, 1905, the Medical Record published my presentation of the etiology of tabes, wherein I compared its pathology with that of syphilis, and presented facts which show that there is no reason which permits one to make syphilis responsible for tabes, but indicate that there is every reason to conclude that we have many other factors which cause tabes. Now, as syphilis does not cause tabes, the treatment of tabes, based on syphilis, could not very well be beneficial, and could lead to nothing else but failure. Errors are not always easily recognized, but that the syphilis theory could hold the profession for such a length of time, with nothing tangible for its support, with not a single cure in its favor, is no credit to those who adhere to the antisyphilitic treatment, despite their knowledge of its inefficiency and harm.

The etiology of tabes shows that, whatever the cause of any given case might be, it induces impairment of nutrition of nerve cells and nerve fibers. Some factors exhaust the blood supply to contingent nerve tissues by overexertion of cells, as in cases due to sexual excesses; other factors impair the nutrition of nerve tissues—by vitiating the blood—to such a degree as to leave them in a weak condition, and when later any strain, which in an individual with a normally nourished cord and brain would not be felt, affects the weak tissues, symptoms of failure begin to appear, as in cases with histories of organic or inorganic poisoning, by infectious diseases, mercury, iodine, lead, etc. Other factors still impair or arrest the nutrition of spinal cord cells and fibers by direct injury to the nutrient blood-vessels, as in traumatic cases.

We therefore have three groups of factors responsible for tabes, and each of them furnishes its varieties. All, however, impair nutrition of nerve tissues, and cause the characteristic pathological condition called tabes, respectively sclerosis. The treatment of tabes must, therefore, begin by preventing impairment of nutrition, and, when impairment has actually set in, by restoring nutrition. To prevent failure of nutrition each patient who has had any infectious disease, who has indulged in sexual excesses, who was subjected to mercury, iodine, lead or any other organic or inorganic poison, or who had any kind of twist of the spine, such as spoken of in the article on the etiology of tabes, should be observed during a period of two or more years, and, as soon as any reflexes, especially those of the patella tendon and eyes, show weakness, the spinal cord and the brain should receive attention by such means as are capable of forcing nutrition of the affected structures. Therefore, the earlier tabes is recognized the greater the chance for a cure, and for this reason it is necessary to be rather too careful than not enough. But what means have we to increase the nutrition of the affected tissues? Considering the task before us of increasing the nutrition of the tabetic lesions, it grows very apparent how useless, or even harmful, every attempt to influence these lesions beneficially by specifics must prove, as none of those, nor any other medicinal agent, has such selective power. Spinal counter-irritation, suspension and rest cure have proved equally futile, and, as it stands to-day, the treatment of tabes presents a chaotic picture of incompetence, discouraging to both physician and patient, but encouraging to charlatanry in various disguises. The only way which holds out hope for success tends toward the employment of such means as will improve the nutrition of the whole system, and of others which will actually increase the nutrition of the affected nerve tissues, and change the pathological conditions to the normal state.

The first step to increase the nutrition of the whole body is taken by placing the patient under most favorable conditions. Pure air, sunshine, congenial surroundings, plenty of sleep, and adequate occupation of mind and body, are most important. Salt-brine friction of the body, in a warm bath, at a temperature agreeable to the patient, twice a week, keeps the pores of the skin open and promotes the circulation. Clothing must aim to keep the body comfortably warm, but not heated. Diet is the next step. It matters not what the patient eats, but what agrees best. The digestive power is generally impaired; slow eating and thorough mastication are, therefore, most essential. Liquids, to wash down the morsels, must be omitted; all solid food must be chewed until sufficiently liquified by the saliva to allow deglutition. Concentrated food must be avoided, as it tends to overload the system with material which it cannot oxidize, and as it also tends to weaken the muscular power of the alimentary canal, and to cause constipation and indigestion. To satisfy the want of the body for water, liquids must be taken between meals. Alcoholic beverages must be avoided, except when the wisdom of the attending physician finds that a temporary stimulation is needed for immediate action.

There is no drug in existence which has any influence beneficial to the tabetic lesions, but when the heart is weak, digitalis, alone or in combination with ergot and strychnine, given in doses and at intervals just sufficient to stimulate the circulation, is indicated. When the digestion is weak, muriatic acid, rhubarb, gentian and nux vomica are very useful. When the bowels do not act, a suitable laxative,

which will help to evacuate the lower bowel, must be found. When the small intestines have lost tone the powdered extract of hydrastis, from two to six grains per day, acts, in most cases, admirably. When the stools are white, the liver is at fault; then about ten drops of the fluid extract of iris versicolor in water, about half an hour before meals and before retiring, is very useful, or one or more grains of calomel with bicarbonate of sodium, before retiring, may be taken. As an all-around tonic a pill composed of two grains each of iron sulphate, sodium carbonate and powdered extract of gentian, 1/8 to 1/4 grain of aloin, 1-32 grain of strychnine sulphate, 1-10 to 1-5 of a grain of ergotin, and two to three drops of tincture of digitalis, taken after meals, and, if necessary, also before retiring, is very beneficial. Any ingredient not needed may be omitted, or substituted, as each case requires. A glance at the above formula shows the intentions: the sulphate of the iron and of the strychnine combines with the sodium, and the iron with the carbonate. The iron disinfects the contents of the alimentary canal, as the feces prove, and acts as a broom to the mucous membranes. The sodium opposes acidity and lubricates the mucous membranes. The sulphate and carbonate check decomposition of foodstuffs in a tardy process of digestion, in which the iron also assists. The consequence of this "house-cleaning" is better absorption and digestion. The sulphate stimulates also the liver cells; the gentian stimulates the peptic glands; the strychnine the nervous system; the ergotin the muscular system, and the digitalis the heart. The aloin, with the assistance of the sulphate and sodium, insures defecation and, being under control by the ergotin, has no congestive effect on the pelvic organs.

The prescription is the proof of a man's skill, and, before a physician writes a prescription for a patient, he must know, not only the pathological condition of the case, but also the needs of the whole system, as indicated by the body in general and by every organ in particular. Idiosyncrasies also demand careful consideration. To treat a pronounced pathological condition only, and to neglect the rest of the whole body, is folly, especially in chronic diseases. Before a lesion like the tabetic can be arrested the whole system must be improved; on the strength of the system rests the hope for recovery. Within the scope of prescription lies all that can be of benefit to the patient; pharmaceutical agents are only a part of the scope, but this part requires painstaking attention, especially in tabes.

Now, while all conditions for the general welfare of the patient are being established, efforts must be made against the tabetic lesion or lesions, and whatever means or agents we might choose to select, we must never forget that the re-establishment of the physiological nutrition of the affected structures is the sole aim. What means have we at our disposal to effect such nutrition? Various means and procedures have been, and are being advocated from time to time, but a short reflection on what has to be accomplished will speedily lead to the recognition of those that are impotent. It would be waste of time to consider, or even to mention, what has no beneficial effect: let us, therefore, consider what can have such effects. The agent which inspires most confidence is electricity. We generate it now in various forms, but I shall divide them all in two classes —first, the current of amperage and low voltage, and, secondly, the current of no amperage and high voltage.

To increase the nutrition of the cord by electricity, both low and high-tension currents are needed; how, depends on the manner in which each treatment is expected to work. The lower the tension and the higher, within therapeutic reason, the amperage, the greater is the electrolytic and the nutritive effect. This effect depends on the polarity of the current. The positive pole of a constant current is acid, astringent and tonic; the negative is alkaline, solvent and relaxing. Furthermore, and in consequence, under the action of the positive pole the fluids of the tissues are driven toward the negative pole, causing depletion at the positive. Under the action of the negative pole fluids are attracted, causing accumulation. All animal tissues, in the state of health, are alkaline in reaction. When nutrition fails the normal alkalinity diminishes in proportion to the acuteness of the pathological focus, with a consequent and progressive tendency to cause shrinkage and hardening of the affected tissues. To arrest this tendency, and then, to extinguish the focus, is what the curative treatment of tabes must aim at. The negative pole of a constant current, therefore, must be placed under the lumbar spine, attached to an electrode, about three inches broad, and about eight inches long, the patient in the recumbent position. On the abdomen I place an electrode that is three or more times larger—it is not material how much larger—and connect it with the positive pole. Now the current is slowly turned on through a rheostat, so as to prevent unpleasant sensation, until the meter registers twenty M. A. Mild currents are nourishing; intense currents are irritating. Each treatment must last not less than thirty minutes, the patient lying with the electrodes undisturbed. During a long treatment the current flows through the body smoothly, pacifying and resting the patient, and inducing the desired chemical changes at the pathological focus. The posterior nerve roots, which are always in an atrophic condition, are benefited first, and despite the fact that the negative pole has a relaxing influence, it strengthens the affected structure, and the patient feels, after each treatment, some degree of beneficial influence. The areas which have been under the action of the poles are quite red, showing the degree of action. Fat or anemic patients show less reaction, and fat patients bear a stronger current with comfort. I always use copper electrodes, covered with thick felt, which latter must absorb water freely, and must always be thoroughly saturated with warm water. The backs of the electrodes are covered with heavy rubber, to confine the current and the water. The binding key must be kept well under the felt and must be covered with a piece of rubber, to prevent concentrated action or burning. A clean towel must always be placed over the wet felt, as the felt absorbs impurities of the skin and loses gradually its absorbing quality, and as it is not in accordance with the rules of hygiene to bring the felt in contact with the skin of various patients. Moreover, the felt irritates the skin, especially when new. After the treatment the areas of the skin which have been subjected to the current must be gently dried with a towel and then rubbed with a little petrolatum, to prevent catching cold.

As stated before, the positive pole of a constant current causes an acid, the negative an alkaline reaction, and each acts on the tissues in the same manner as acid or alkaline solutions do, but there is a great difference between an electrolytic and a simple chemical action. When the current starts to flow through the body the impulse proceeds from the positive electrode toward the negative, and the electrodes

form the bases of the polar zones, from which the electrolytic action proceeds to reach the opposite. As the current is turned on each pole attempts to overcome all obstructions—resistance—to establish communication. As soon as communication is established each pole proceeds to reach its opposite by actual contact, and, to accomplish this, it attracts, according to its strength, material of its kind from the nearest tissues, and places it in line toward the opposite. Under the positive pole all acid principles, and under the negative all alkaline principles, are attracted, and the longer the current flows the more material is placed in front of each pole, increasing the depth of the polar zones and so shortening the interpolar zone. Now, while this polar activity lasts, we see how, under the action of the positive, the tissues contract, and how they expand under the negative. If you cut a potato in half and stick the tips of the electrodes of a constant current battery in it, a little apart from each other, and turn the current on, you soon see the potato substance at the positive pole growing green and contracting, and at the negative growing white, expanding and bubbling. When we remove the positive pole we find it firm in the substance and corroded, while the negative is quite loose and bright. This is a simple experiment, and it also distinguishes, in case of doubt, the positive from the negative. This electrochemical process offers us, therefore, by its polarity, two potent agents which grow more and more potent in our hands as experience increases, and teaches us how and when to employ them in pathological conditions. But, in order to employ polarity with benefit against diseases, the physician must know the pathology of each disease, its site, and that pathological foci grow to be such by deviation of the chemical condition from normal.

Besides the polar effects, the constant current, if properly employed, exerts a highly beneficial biological influence on the whole body, which pacifies the nervous system and strengthens the nerve centers for their duties. To increase the nutrition of the brain I place under the occipito-cervical region an electrode large enough for the area, and connect it with the positive pole, the patient being in the recumbent position; then I cover the orbital regions and nose with a strip of clean linen, and over each eye I place a thick pad of absorbent cotton, well saturated with cold water. Now I place over the pads the electrode, which is, practically, a spectacle frame, but instead of glasses it has two slightly concave copper plates as large as the eyes. To secure proper action of the current all electrodes, wherever placed, must be weighted down, to establish capillary attraction. To both ends of the eye electrode strings are attached, which are led around the occiput, where they cross each other; then I tie both ends of the strings over the electrode, so as to effect the desired pressure without discomfort to the patient. Now I connect the eye electrode with the negative pole, and turn the current gently and slowly on, until the meter shows five milliamperes. I seldom go over ten milliamperes, and not often so high. With ten milliamperes and thick pads the application can be made for thirty minutes. After the patient has received about ten treatments to the spinal cord, I give about five treatments to the brain. By this time the patient will volunteer the information that he feels stronger in his legs, clearer in his head, and that he sees better.

To stimulate nutrition at the pathological foci still more, and to give the tissues rest from the galvanic current, I employ the high-tension current through a Geissler tube, also bipolar. For the spinal cord one electrode rests, as for the galvanic treatment, under the lumbar spine, and is connected with the pole of negative direction, the other electrode, a cylinder of metal or glass, is inserted, for males into the rectum, for females into the vagina, and connected with the pole of positive direction. For the brain the electrodes are also applied as for the galvanic current; the positive direction of the current is connected to the electrode under the occipito-cervical region, the negative direction to the electrode over the eyes. At each sitting I allow this current to flow about fifteen minutes to the spine, and about five to ten minutes to the brain. There is but little sensation connected with this current, and it appears, therefore, harmless, but it has after-effects which, in some patients, are quite marked and show themselves by peculiar sensations in the lower extremities and in the head. It is, therefore, better to begin with low pressure and short treatments, to avoid any unpleasant reaction. Three to five high-tension current treatments in succession, every other day, is all that is required from time to time. High-tension currents have no polarity, but they have direction. When you place an old style Geissler tube in the circuit, you will perceive that the bulb at one end is filled with a cloud of colored light, but that the bulb at the other end is empty; and you will further find that the empty bulb is connected with the positive element of the battery and the filled bulb with the negative element. I, therefore, speak of positive and negative direction. I observed this phenomena when a boy, during lectures on and demonstrations of physical forces, and remembered it when I began to employ electricity, fifteen years ago. It occurred to me then that if the pressure from the positive pole was strong enough to keep its bulb empty and that as the negative filled, that it then could also have a propelling force on the fluids of the body, and should be useful in depleting congested areas, or forcing nutrition where it was impaired. And I found that all high-tension currents had, actually, the expected effect; but through a tube this effect is increased and sensation diminished. Moreover, this tube by its bulb, acts, like the potato, as a reliable indicator of positive and negative direction of any induced current, from coils energized by a constant current, and having from ten to thirty thousand feet of wire. Too high pressure fills both bulbs of a small tube and fails to show the direction.

To increase the nutrition of the muscular and peripheral nerves I employ the faradic current. When I treat the anterior surface of the body the patient is in the recumbent position, with an electrode, connected to the negative element of the battery, under the whole spine. The positive element of the battery is connected to a round disk electrode, covered with absorbent cotton, well saturated with warm water. With this round electrode, about the size of a silver dollar, I work over the whole anterior surface of the body, from the head down to the toes. Then the patient turns face down, the stabile electrode now under the abdomen, and the whole procedure is repeated on the posterior surface of the body, from the occiput to the toes. Each treatment takes about thirty minutes, and for each new cotton is used. Now and then I use the constant current in the same way. These treatments are quite stimulating, but care must be taken that the patient does not catch cold. For this reason the operating chair is covered with heavy cotton-flannel sheets. The presenting surface of the body is also well covered with such sheets, except the part just under treatment, which is immediately dried with a towel by the office-nurse, after another part is taken under treatment, and covered as soon as dried. These general treatments I give about

once per week between the regular galvanic or Geissler application. All conducting cords are covered by rubber-tubing, to prevent escape of current and annoyance to the patient. During the last two years I have been using also the alternating street current through a transformer, which is practically a faradic apparatus with a secondary coil. This current has considerable amperage, which can be increased or diminished, according to the length and caliber of the wire in the secondary coil. Various binding posts, connected with certain sections of the coil, and the movability of the coil, allow an endless variety of the current, to meet any intention. I also use this current at times for general surface treatment, and at times stabile instead of the galvanic. As a rule I give three treatments per week, and keep a record of each treatment. Before I treat a patient I ask how he felt after the last treatment and how he feels generally. All information the patient gives I record also, and decide then what the next treatment shall be.

Vibration of the spine appears as a logical therapeutic agent in tabes, and manufacturers, and those interested in the sale of vibrators, exert themselves considerably to obtain testimony from physicians to prove that it cures tabes and every other ailment human flesh is heir to, but all that can be said in favor of vibration is, that it is somewhat stimulating, if judiciously applied, and that it is beneficial to tissues in any part of the body to about the same degree as massage. Vibration has advantages over massage in some directions, and massage has advantages over vibration in other directions; the modus operandi differs in both, but the effect is practically the same.
